Abstract

In the first part of the paper, two consolidated hybrid observer designs for non-hybrid systems are presented. In the second part, recently results available in the literature related to the observability and observer design for different classes of hybrid systems are introduced.

Keywords

Introduction

Observers design, which are used to estimate the unmeasured plant state, has received a lot of attention since the late '60s. One of the first leading contribution to clearly formalize the estimation problem and propose a solution in the linear case has been proposed by Luenberger (1966). The recipe to implement a Luenberger-type observer for a continuous-time linear system described by

$$\dot{x} = Ax + Bu, \quad y = Cx + Du, \qquad (1)$$

with $x \in \mathbb{R}^n, u \in \mathbb{R}^p, y \in \mathbb{R}^m, A \in \mathbb{R}^{n \times n}, B \in \mathbb{R}^{n \times p}, C \in \mathbb{R}^{m \times n}$, and $D \in \mathbb{R}^{m \times p}$, has three main ingredients: system data, the correction term commonly referred to as *output injection*, and the *observability/detectability/determinability* conditions. A Luenberger-type observer for (1), which consists in a copy of the (system data) dynamics (1) with a linear correction term $\mathbf{L}(\mathbf{y} - \hat{\mathbf{y}})$, is given by

$$\dot{\hat{x}} = A\hat{x} + Bu + \mathbf{L}(\mathbf{y} - \hat{\mathbf{y}}), \quad \hat{y} = C\hat{x} + Du, \quad (2)$$

with $L \in \mathbb{R}^{n \times m}$ and where $\hat{x}$ is the estimated value of x. The estimation error $e = x - \hat{x}$ satisfies the differential equation $\dot{e} = (A - LC)e$ with initial condition $e(0) = x(0) - \hat{x}(0)$. Since the observer has a copy of the plant dynamics and the correction term is $L(y - \hat{y}) = LCe$, the zero estimation error manifold $x = \hat{x}$ is invariant (if $x(0) = \hat{x}(0)$, then $e(t) \equiv 0$ for all $t \geq 0$), whereas its *attractivity* (yielding global exponential stability of the estimation error system) requires $A - LC$ be Hurwitz. Such an L, if A

is not already Hurwitz, exists if the pair (A, C) is *detectable* or (sufficient condition) *observable*. The observer in (2) exploits only the injection term in the for continuous time dynamics (flow map), and one may ask how profitable could be *resets* of the observer state (jump map) designing a *hybrid observer*.

The observer design for hybrid systems is a relatively new area of research and results are consolidated only for few classes of linear hybrid systems.

In section "Continuous-Time Plants," a hybrid redesign of the observer (2) is discussed first and then a more general design for nonlinear systems is introduced, whereas in section "Systems with Flows and Jumps" the recent results related to observability and observer designs for hybrid systems is discussed. Conclusions are given in section "Summary and Future Directions."

Hybrid Observers: Different Strategies

The community of researchers working on hybrid observer, which is a quite recent area and is the subject of growing interest, is wide and a unique formal definition/notation has not been reached yet. This fact is strictly related to the large number of different hybrid system models that are currently adopted by researchers. To render as simple as possible this short presentation, we let the state $x(t)$ of a hybrid system be driven by the flow map (differential equation) when $t \neq t_j$ and by the jump map (difference equation) when $t = t_j$, with $x(t)$ right continuous, i.e., $\lim_{t \to t_j^+} x(t) = x(t_j)$.

Continuous-Time Plants

Linear Case
A simple strategy to improve convergence to zero of the estimation error for (1) has been proposed in Raff and Allgower (2008) and consists in resetting the observer state x, at predetermined fixed time intervals t_j, by means of

the linear correction term $\mathbf{K(t)}\,(\mathbf{y(t)} - \mathbf{C\hat{x}(t)})$ at jump times, yielding

$$\dot{\hat{x}}(t) = A\hat{x}(t) + Bu(t) + \mathbf{L}\,(\mathbf{y(t)} - \mathbf{C\hat{x}(t)}),$$
(3a)

$$\hat{x}(t_j) = x\left(t_j^-\right) + \mathbf{K\left(t_j^-\right)}\,\left(\mathbf{y\left(t_j^-\right)} - \mathbf{C\hat{x}\left(t_j^-\right)}\right),$$
(3b)

where $t_0 = 0$, $t_{j+1} - t_j = T > 0$, $j \in \mathbb{N}_{\geq 1}$ and T is a parameter that defines the interval times between resets and has to be chosen such that

$$Im\left(\lambda_p - \lambda_r\right)T \neq 2r\pi, \ r \in \mathbb{Z}\backslash\{0\}, \quad (4)$$

for each pair (λ_p, λ_r) of complex eigenvalues of the matrix $A - LC$. This preserves the (continuous time or flow) observability of the system (1) when sampled at time instants t_j and allows to select a matrix K_0 such that $(I - K_0C)\exp((A - LC)\,T)$ has all its eigenvalues at zero. Then, the estimation error $e(t)$ converges to zero in finite time (nT) if (1) is observable and the matrix $K(t) : \mathbb{R}_{\geq 0} \to \mathbb{R}^{n \times q}$ is selected such as $K(t) = K_0$ if $t \leq t_n$ and $K(t) = 0$ otherwise. It is important to note that the state reset (3b) yields a hybrid estimation error system given by

$$\dot{e}(t) = (A - LC)\,e(t), \quad (5a)$$

$$e(t_j) = \left(I - K\left(t_j^-\right)C\right)e\left(t_j^-\right). \quad (5b)$$

The stability property of the origin can be easily deduced by noting that

$$e(t_j) = \prod_{k=1}^{j}\left(I - K\left(t_j^-\right)C\right)$$
$$\exp\left((A - LC)\,T\right)e(0),$$

and given that $(I - K_0C)\exp((A - LC)\,T)$ is nilpotent, then $e(t_n) = e(nT) = 0$.

The potentiality benefits of hybrid observers to improve the performances of classic continuous-time observer is a relatively new area of research. Along this line, the recent work

proposed in Prieur et al. (2012) allows to limit the *peaking phenomena* for a class of *high-gain observers* opportunely resetting its (augmented) state. Moreover, when the output of (1) is a nonlinear function of the state, $y = h(x)$, with $h(\cdot)$ not invertible (e.g. the saturation function), it would be possible to rewrite (1) as a hybrid system with linear flow map and augmented state designing a hybrid observer as in Carnevale and Astolfi (2009).

Nonlinear Case

When the input of a continuous-time plant is piecewise-constant the hybrid observer proposed in Moraal and Grizzle (1995), exploiting sampled measurements, can be successfully applied for a class of nonlinear continuous (or discrete-time) systems

$$\dot{x} = f(x(t), u(t)), \, y(t) = h(x(t), u(t)), \tag{6}$$

with sufficiently smooth maps $f(\cdot, \cdot)$ and $h(\cdot, \cdot)$ and where

$$x(t_j) = F(x(t_{j-1}), u(t_{j-1})), \tag{7}$$

is the sample-data (discrete-time) version of (6) with sampling time $T = t_{j-1} - t_j$. Then, it is possible to define a hybrid observer of the following type:

$$\dot{\hat{x}}(t) = f(\hat{x}(t), u(t)), \tag{8a}$$

$$\hat{x}(t_j) = \Gamma\left(y\left(t_j^-\right), \hat{x}\left(t_j^-\right), \xi\left(t_j^-\right)\right), \tag{8b}$$

where the reset map Γ and the dynamics of the new variable $\xi(t)$ have to be properly defined. The main idea in Moraal and Grizzle (1995) is that the Newton method, in continuous and discrete time, can be used to estimate the value of ξ that renders zero the function

$$W_j^N(\xi) = Y_j^N - H\left(\xi, U_j^N\right), \tag{9}$$

where $U_j^N = \left[u'(t_{j-N+1}), \ldots, u'(t_j)\right]'$ and $Y_j^N = \left[y'(t_{j-N+1}), \ldots, y'(t_j)\right]'$ are the sampled input and output vectors, respectively, and $H : \mathbb{R}^n \times \mathbb{R}^{m \times N} \to \mathbb{R}^N$ maps the state $x(t_j)$ and the N-tuple of control inputs U_j^N into the output vector Y_j^N, i.e., $H\left(x(t_j), U_j^N\right) = Y_j^N$, and is defined as

$$H\left(x, U_j^N\right) \triangleq \begin{bmatrix} h\left(F^{-1}\left(F^{-1}(\ldots), u(t_{j-N+1})\right), u(t_{j-N+1})\right) \\ \vdots \\ h\left(F^{-1}(x, u(t_{j-1})), u(t_{j-1})\right) \\ h(x, u(t_j)) \end{bmatrix}, \tag{10}$$

where F^{-1} shortly represents the inverse of the map F such that $x(t_{j-1}) = F^{-1}(x(t_j), u(t_{j-1}))$.

The system (6)–(7) is said to be *N-osbervable,* for some $N \geq 1$ (the generic selection is $N = 2n + 1$), when $W_j^N(\xi) = 0$ hold only if $\xi = x(t_j)$, uniformly in U_j^N. Then, under certain technical assumptions (see Moraal and Grizzle 1995) related to the derivatives of f and h and the invertibility of the Jacobian matrix $J(x) = \partial H(x)/\partial x$, it is possible to select

$$\dot{\xi}(t) = kJ(\xi(t))^{-1}\left(Y_j^N \right.$$

$$\left. -H\left(\xi(t), U_j^N\right)\right), \tag{11a}$$

$$\xi(t_j) = F\left(\xi\left(t_j^-\right), u(t_{j-1})\right), \tag{11b}$$

with a sufficiently high-gain $k > 0$ and the reset map $\Gamma(\cdot) = F\left(\xi\left(t_j^-\right), u(t_{j-1})\right)$. Note that (11a) is commonly referred to as Newton flow. This approach could be easily extended to other

continuous-time minimization algorithms (normalized gradient, line-search, etc.) changing the rhs of (11a) or even with discrete-time methods iterated at higher frequency within the sample time T, yielding faster convergence to zero of the estimation error.

The same approach can be used when a continuous-time observer for (6) is considered in place of (8a) and the Newton-based resets can be used to possibly improve the performances. The continuous and discrete-time Newton algorithm require the knowledge of the jump map F to define (7), i.e. the exact discrete time model of (6), and the Jacobian matrix $J(x) = \partial H(x)/\partial x$. An approach that do not require such knowledge is proposed in Biyik and Arcak (2006), where continuous time filters and secant method allow to estimate (numerically) the map F and the Jacobian matrix, or in Sassano et al. (2011) where an *extremum-seeking*-based technique is considered.

A different approach to estimate the state of a continuous-time plant, pursued for example in Ahrens and Khalil (2009) and Liu (1997), exploits switching output injections, letting the correction term $l_\sigma(\cdot)$ to switch among opportune values selected by a suitable definition (often derived by a Lyapunov-based proof) of the switching signal $\sigma(t)$. These switching gains allow to improve observer performances and robustness against measurement noise and model uncertainties.

Systems with Flows and Jumps

The classical notion of observability does not hold for hybrid systems. As an example, consider the autonomous linear hybrid system described by $\dot{x}(t) = Ax(t)$ and $x(t_j) = Jx(t_j^-)$ with

$$A = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad J = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{bmatrix}, \quad (12)$$

and $C = [0, 1, 0]$. Evidently the flow is not observable in the classic sense given that $\mathcal{O}_{\text{flow}} = \begin{bmatrix} C', (CA)', (CA^2)' \end{bmatrix}'$ is not full rank and the flow-unobservable subspace

is $\ker(\mathcal{O}_{\text{flow}}) \triangleq \{x \in \mathbb{R}^3 : x_2 = x_3 = 0\}$. Nevertheless, in the first flow time interval $\tau = t_1 - t_0$, it is possible to estimate (e.g. in finite time using the observability Gramian matrix) the initial conditions $(x_2(t_0), x_3(t_0))$. Then when the first jump take place at time t_1, thanks to the structure of the jump map J that resets the value of $x_3(t_1)$ with the flow-unobservable $x_1(t_1^-)$, it is possible to estimate in the next flow time interval the value of $x_1(t_1^-)$ so that the initial condition $x(t_0)$ can be completely determined. The hybrid observability matrix in this case has the following expression

$$\mathcal{O}_{\text{hybrid}} = \begin{bmatrix} \mathcal{O}'_{flow}, (\mathcal{O}_{flow} Je^{AT_1})', \\ (\mathcal{O}_{flow}(Je^{AT_2})^2)' \end{bmatrix}'$$

and is full rank for all $T_j = t_j - t_{j-1}$ that satisfies (4). Note that from a practical point of view, in this case the time interval that allows to reconstruct the complete state is $[t_0, t_1 + \epsilon)$ since the observer needs at least an ϵ time of the new measurements (after the first jump) to evaluate the full state $\begin{bmatrix} \mathcal{O}'_{flow}, (\mathcal{O}_{flow} Je^{AT_1})', (\mathcal{O}_{flow}(Je^{AT_2})^2)' \end{bmatrix}'$. This simple example suggests that (impulsive) hybrid systems might have a reacher notion of observability than the classical ones. These properties have been studied also for mechanical systems subject to non-smooth impacts in Martinelli et al. (2004), where a high-gain-like observer design has been proposed assuming the knowledge of the impact times t_i, no *Zeno* phenomena (no finite accumulation point for t_j's), and a minimum *dwell-time,* $t_{j+1} - t_j \geq \delta > 0$. With the aforementioned assumptions and considering the more general class of hybrid system described by

$$\dot{x}(t) = f(x, u),$$
$$x(t_j) = g\left(x\left(t_j^-\right), u\left(t_j^-\right)\right), \quad (13)$$

with $y = h(x,u)$, a frequent choice is to consider the hybrid observer of the form

$$\dot{\hat{x}}(t) = f(\hat{x}, u) + \mathbf{l}(\mathbf{y}, \mathbf{x}, \mathbf{u}), \quad (14a)$$

$$\hat{x}\left(t_j\right) = g\left(\hat{x}\left(t_j^-\right), u\left(t_j^-\right)\right)$$
$$+ \mathbf{m}\left(\hat{\mathbf{x}}\left(\mathbf{t_j^-}\right), \mathbf{u}\left(\mathbf{t_j^-}\right)\right), \quad (14b)$$

with $\mathbf{l}(\cdot)$ and $\mathbf{m}(\cdot)$ that are zero when $\hat{x} = x$ rendering flow and jump-invariant the manifold $\hat{x} = x$ relying only on the correction term $l(\cdot)$ ($m \equiv 0$) in a high-gain-like design during the flow. The correction during the flow has to recover, within the minimum dwell-time δ, the worst deterioration of the estimation error induced by the jumps (if any) and the transients such that $\left\| e\left(t_{j+1}\right) \right\| < \left\| e\left(t_j^-\right) \right\|$ or $V\left(e\left(t_{j+1}\right)\right) < V\left(e\left(t_j^-\right)\right)$ if a Lyapunov analysis is considered. This type of observer design, with $m = 0$ and the linear choice $l(y, \hat{x}, u) = L(y - M\hat{x})$, have been proposed in Heemels et al. (2011) for *linear complementarity systems* (LCS) in the presence of state jumps induced by impulsive input. Therein, solutions of LCS are characterized by means of piecewise Bohl distributions and the specially defined *well-posedness* and *low-index* properties, which combined with passivity-based arguments, allow to design a global hybrid observer with exponential convergence. A separation principle to design an output feedback controller is also proposed.

An interesting approach is pursued in Forni et al. (2003) where global output tracking results on a class of linear hybrid systems subject to impacts is introduced. Therein, the key ingredient is the definition of a "mirrored" tracking reference (a change of coordinate) that depends on the sequence of different jumps between the desired trajectory (a virtual bouncing ball) and the plant (the controlled ball). Exploiting this (time-varying) change of coordinates and assuming that the impact times are known, it is possible to define an estimation error that is not discontinuous even when the tracked ball has a bounce (state jump) and the plant does not. A time regularization is included in the model embedding a minimum dwell-time among jumps. In this way, it is possible to design a linear hybrid observer represented by (14) with a linear (mirrored) term $l(\cdot)$ and $m(\cdot) \equiv 0$, proving (by standard quadratic Lyapunov functions) that the

origin of the estimation error system is GES. In this case, the standard observability condition for the couple (A, C) is required.

Switching Systems and Hybrid Automata

Switching systems and hybrid automata have been the subject of intense study of many researchers in the last two decades. For these class of systems, there is a neat separation $x = [z, q]'$ among purely discrete-time state q (*switching signal or system mode*) and rest of the state z that generically can both flow and jump. The observability of the entire system is often divided into the problem of determining the switching signal q first and then z. The switching signal can be divided into two categories: arbitrary (*universal problem*) or specific (*existential problems*) switchings.

In Vidal et al. (2003) the observability of autonomous linear switched systems with no state jump, minimum dwell time, and unknown switching signal is analyzed. Necessary and sufficient observability conditions based on rank tests and output discontinuities detection strategies are given. Along the same line, the results are extended in Babaali and Pappas (2005) to non-autonomous switched systems with non-Zeno solutions and without the minimum dwell-time requirement, providing state z and mode q observability characterized by linear-algebraic conditions.

Luenberger-type observers with two distinct gain matrices L_1 and L_2 are proposed in the case of bimodal piecewise linear systems in Juloski et al. (2007) (where state jumps are considered), whereas recently in Tanwani et al. (2013), algebraic observability conditions and observer design are proposed for switched linear systems admitting state jumps with known switching signal (although some asynchronism between the observer and the plant switches is allowed). Results related to the observability of hybrid automata, which include switching systems, can be found in Balluchi et al. (2002) and the related references. Therein the *location observer* estimates first the system *current location q*, processing system input and output assuming that it is *current-location observable*, a property that

is related to the system *current-location observation tree*. This graph is iteratively explored at each new input to determine the node associated to the current value of $q(t)$. Then, a linear (switched) Luenberger-type observer for the estimation of the state z, assuming minimum dwell-time and observability of each pair (A_q, C_q), is proposed.

Summary and Future Directions

Observer design and observability properties of general hybrid systems is an active field of research and a number of different results have been proposed although not consolidated as for classical linear systems. The results are based on different notations and definitions for hybrid systems. Efforts to provide a unified approach, in many case considering the general framework for hybrid systems proposed in Goebel et al. (2009), is pursued by the scientific community to improve consistency and cohesion of the general results. Observer designs, observability properties, and separation principle even with linear flow and jump maps are not yet completely characterized and, in the nonlinear case, only few works have been proposed (see Teel (2010)), providing open challenges for the scientific community.

Abstract

We explore the problem of identification and control of living cell populations. We describe how de novo control systems can be interfaced with living cells and used to control their behavior. Using computer controlled light pulses in combination with a genetically encoded light-responsive module and a flow cytometer, we demonstrate how in silico feedback control can be configured to achieve precise and robust set point regulation of gene expression. We also outline how external control inputs can be used in experimental design to improve our understanding of the underlying biochemical processes.

Keywords

Introduction

Control systems, particularly those that employ feedback strategies, have been used successfully in engineered systems for centuries. But natural feedback circuits evolved in living organisms much earlier, as they were needed for regulating the internal milieu of the early cells. Owing to modern genetic methods, engineered feedback control systems can now be used to control in real-time biological systems, much like they control any other process. The challenges of controlling living organisms are unique. To be successful, suitable sensors must be used to measure the output of a single cell (or a sample of cells in a population), actuators are needed to affect control action at the cellular level, and a controller that connects the two should be suitably designed. As a model-based approach is needed for effective control, methods for identification of models of cellular dynamics are also needed. In this entry, we give a brief overview of the problem of identification and control of living cells. We discuss the dynamic model that can be used, as well as the practical aspects of selecting sensor and actuators. The control systems can either be realized on a computer (in silico feedback) or through genetic manipulations (in vivo feedback). As an example, we describe how de novo control systems can be interfaced with living cells and used to control their behavior. Using computer controlled light pulses in combination with a genetically encoded light-responsive module and a flow cytometer, we demonstrate how in silico feedback control can

be configured to achieve precise and robust set point regulation of gene expression.

Dynamical Models of Cell Populations

In this entry, we focus on a model of an essential biological process: gene expression. The goal is to come up with a mathematical model for gene expression that can be used for model-based control. Due to cell variability, we will work with a model that describes the average concentration of the product of gene expression (the regulated variable). This allows us to use population measurements and treat them as measurements of the regulated variable. We refer the reader to the entry ▶ Stochastic Description of Biochemical Networks in this encyclopedia for more information on stochastic models of biochemical reaction networks. In this framework, the model consist of an N-vector stochastic process $X(t)$ describing the number of molecules of each chemical species of interest in a cell. Given the chemical reactions in which these species are involve, the mean, $E[X(t)]$, of $X(t)$ evolves according to deterministic equations described by

$$\dot{E}[X(t)] = SE[w(X(t))],$$

where S is an $N \times M$ matrix that describes the stoichiometry of the M reactions described in the model, while $w(\cdot)$ is an M-vector of propensity functions. The propensity functions reflect the rate of the reactions being modeled. When one considers elementary reactions (see ▶ Stochastic Description of Biochemical Networks), the propensity function of the ith reaction, $w_i(\cdot)$, is a quadratic function of the form $w_i(x) = a_i + b_i^T x + c_i x^T Q_i x$. Typically, w_i is either a constant: $w_i(x) = a$, a linear function of the form $w_i(x) = b x_j$ or a simple quadratic of the form $w_i(x) = c x_j^2$. Following the same procedure, similar dynamical models can be derived that describe the evolution of higher-order moments (variances, covariances, third-order moments, etc.) of the stochastic process $X(t)$.

Identification of Cell Population Models

The model structure outlined above captures the fundamental information about the chemical reactions of interest. The model parameters that enter the functions $w_i(x)$ reflect the reaction rates, which are typically unknown. Moreover, these reaction rates often vary between different cells, because, for example, they depend on the local cell environment, or on unmodeled chemical species whose numbers differ from cell to cell (Swain et al. 2002). The combination of this extrinsic parameter variability with the intrinsic uncertainty of the stochastic process $X(t)$ makes the identification of the values of these parameters especially challenging.

To address this combination of intrinsic and extrinsic variabilities, one can compute the moments of the stochastic process $X(t)$ together with the cross moments of $X(t)$ and the extrinsic variability. In the process, the moments of the parametric uncertainty themselves become parameters of the extended system of ordinary differential equations and can, in principle, be identified from data. Even though doing so requires solving a challenging optimization problem, effective results can often be obtained by randomized optimization methods. For example, Zechner et al. (2012) presents the successful application of this approach to a complex model of the system regulating osmotic stress response in yeast.

When external signals are available, or when one would like to determine what species to measure when, such moment-based methods can also be used in experiment design. The aim here is to determine a priori which perturbation signals and which measurements will maximize the information on the underlying chemical process that can be extracted from experimental data, reducing the risk of conducting expensive but uninformative experiments. One can show that, given a tentative model for the biochemical process, the moments of the stochastic process $X(t)$ (and cross $X(t)$-parameter moments in the presence of extrinsic variability) can be used to approximate the Fischer information matrix and hence characterize

the information that particular experiments contain about the model parameters; an approximation of the Fischer information based on the first two moments was derived in Komorowski et al. (2011) and an improved estimate using correction terms based on moments up to order 4 was derived in Ruess et al. (2013). Once an estimate of the Fischer information matrix is available, one can design experiments to maximize the information gained about the parameters of the model. The resulting optimization problem (over an appropriate parametrization of the space of possible experiments) is again challenging but can be approached by randomized optimization methods.

Control of Cell Populations

There are two control strategies that one can implement. The control systems can be realized on a computer, using real-time measurements from the cell population to be controlled. These cells must be equipped with actuators that respond to the computer signals that close the feedback loop. We will refer to this as *in silico feedback*. Alternatively, one can implement the sensors, actuators, and control system in the entirety within the machinery of the living cells. At least in principle, this can be achieved through genetic manipulation techniques that are common in synthetic biology. We shall refer to this type of control as *in vivo feedback*. Of course some combination of the two strategies can be envisioned. In vivo feedback is generally more difficult to implement, as it involves working within the noisy uncertain environment of the cell and requires implementations that are biochemical in nature. Such controllers will work autonomously and are heritable, which could prove advantageous in some applications. Moreover, coupled with intercellular signaling mechanisms such as quorum sensing, in vivo feedback may lead to tighter regulation (e.g., reduced variance) of the cell population. On the other hand, in silico controllers are much easier to program, debug, and implement and can have much more complex dynamics that would be possible with in vivo

controllers. However, in silico controllers require a setup that maintains contact with all the cells to be controlled and cannot independently control large numbers of such cells. In this entry we focus exclusively on in silico controllers.

The Actuator

There could be several ways to send actuating signals into living cells. One consists of chemical inducers that the cells respond to either through receptors outside the cell or through translocation of the inducer molecules across the cellular membrane. The chemical signal captured by these inducers is then transduced to affect gene expression. Another approach we will describe here is induction through light. There are several light systems that can be used. One of these includes a light-sensitive protein called phytochrome B (PhyB). When red light of wavelength 650 nm is shined on PhyB in the presence of phycocyanobilin (PCB) chromophore, it is activated. In this active state it binds to another protein Pif3 with high affinity forming PhyB-Pif3 complex. If then a far-red light (730 nm) is shined, PhyB is deactivated and it dissociates from Pif3. This can be exploited for controlling gene expression as follows: PhyB is fused to a GAL4 binding domain (GAL4BD), which then binds to DNA in a specific site just upstream of the gene of interest. Pif3 in turn is fused to a GAL4 activating domain (GAL4AD). Upon red light induction, Pif3-Gal4AD complex is recruited to PhyB, where Gal4AD acts as a transcription factor to initiate gene expression. After far-red light is shined, the dissociation of GAL4BD-PhyB complex with Pif3-Gal4AD means that Gal4AD no longer activates gene expression, and the gene is off. This way, one can control gene expression – at least in open loop.

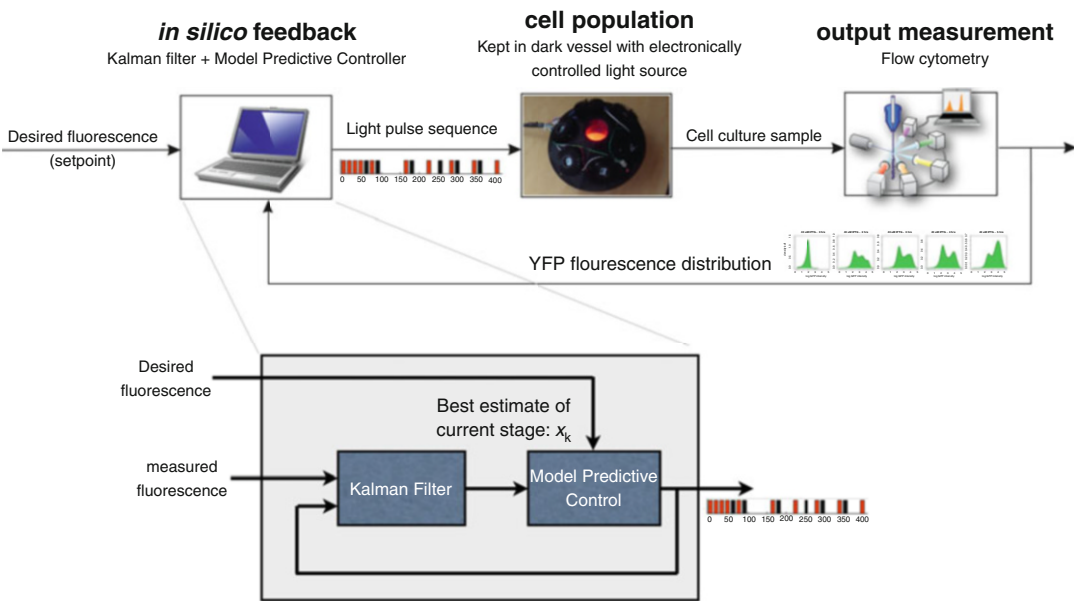
The Sensor

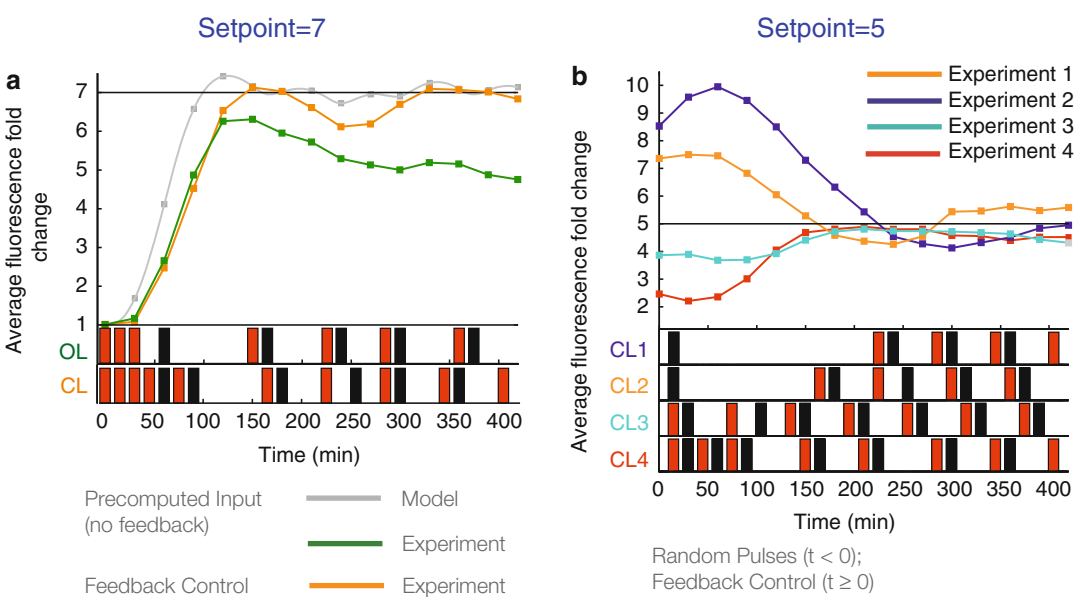
To measure the output protein concentration in cell populations, a florescent protein tag is needed. This tag can be fused to the protein of interest, and the fluorescence intensity emanating from each cell is a direct measure of the protein concentration in that cell. There are several technologies for measuring fluorescence of cell
Identification and Control of Cell Populations, Fig. 1
Top figure: shows a yeast cell whose gene expression can be induced by light: red light turns on gene expression while far-red turns it off. Bottom figure: Each input light sequences can be applied to a culture of light responsive yeast cells resulting in a corresponding gene expression pattern that is measured by flow cytometry. By applying multiple carefully chosen light input test sequences and looking at their corresponding gene expression patterns a dynamic model of gene expression can be identified

populations. While fluorimeters measure the overall intensity of a population, flow cytometry and microscopy can measure the fluorescence of each individual cell in a population sample at a given time. This provides a snapshot measurement of the probability density function of the protein across the population. Repeated measurements over time can be used as a basis for model identification (Fig. 1).

The Control System

Equipped with sensors, actuators, and a model identified with the methods outlined above one can proceed to design control algorithms to regulate the behavior of living cells. Even though moment equations lead to models that look like conventional ordinary differential equations, from a control theory point of view, cell population systems offer a number of challenges. Biochemical processes, especially genetic regulation, are often very slow with time constants of the order of tens of minutes. This suggests that pure feedback control without some form of preview may be insufficient. Moreover, due to our incomplete understanding of the underlying biology, the available models are typically inaccurate, or even structurally wrong. Finally, the control signals are often unconventional; for example, for the light control system outlined above, experimental limitations imply that the system must be controlled using discrete light pulses, rather than continuous signals.

Fortunately advances in control theory allow one to effectively tackle most of these challenges. The availability of a model, for example, enables the use of model predictive control methods that introduce the necessary preview into the feedback process. The presence of unconventional inputs may make the resulting optimization problems difficult, but the slow dynamics work in our favor,


Identification and Control of Cell Populations, Fig. 2 Architecture of the closed-loop light control system. Cells are kept darkness until they are exposed to light pulse sequences from the in silico feedback controller. Cell culture samples are passed to the flow cytometer whose output is fed back to the computer which implements a Kalman filter plus a Model Predictive Controller. The objective of the control is to have the mean gene expression level follow a desired set value


Identification and Control of Cell Populations, Fig. 3 Left panel: The closed-loop control strategy (orange) enables set point tracking, whereas an open-loop strategy (green) does not. Right panel: Four different experiments, each with a different initial condition. Closed-loop control is turned on at time t=0 shows that tracking can be achieved regardless of initial condition. (See Milias-Argeitis et al. (2011))

providing time to search the space of possible input trajectories. Finally, the fundamental principle of feedback is often enough to deal with inaccurate models. Unlike systems biology applications where the goal is to develop a model that faithfully captures the biology, in population control applications even an inaccurate model is often enough to provide adequate closed-loop performance. Exploring these issues, Milias-Argeitis et al. (2011) developed a feedback mechanism for genetic regulation using the light control system, based on an extended Kalman filter and a model predictive controller (Figs. 2 and 3). A related approach was taken in Uhlendorf et al. (2012) to regulate the osmotic stress response in yeast, while Toettcher et al. (2011) develop what is affectively a PI controller for a faster cell signaling system.

Summary and Future Directions

The control of cell populations offers novel challenges and novel vistas for control engineering as well as for systems and synthetic biology. Using external input signals and experiment design methods, one can more effectively probe biological systems to force them to reveal their secrets. Regulating cell populations in a feedback manner opens new possibilities for biotechnology applications, among them the reliable and efficient production of antibiotics and biofuels using bacteria. Beyond biology, the control of populations is bound to find further applications in the control of large-scale, multi-agent systems, including those in transportation, demand response schemes in energy systems, crowd control in emergencies, and education.

Industrial MPC of Continuous Processes

Mark L. Darby
CMiD Solutions, Houston, TX, USA

Abstract

Model predictive control (MPC) has become the standard for implementing constrained, multivariable control of industrial continuous processes. These are processes which are designed to operate around nominal steady-state values, which include many of the important processes found in the refining and chemical industries. The following provides an overview

of MPC, including its history, major technical developments, and how MPC is applied today in practice. Possible future developments are provided.

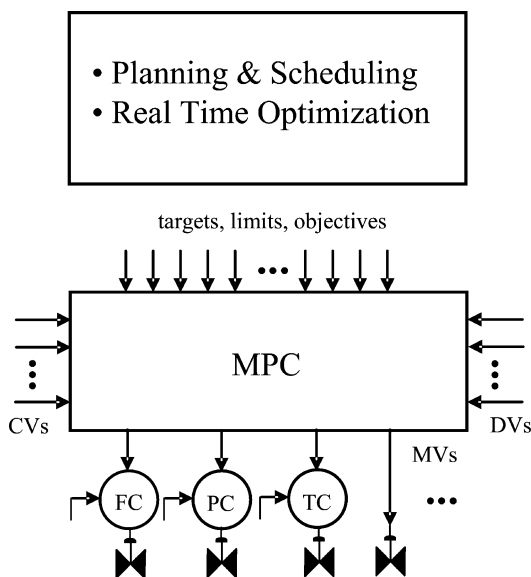
Keywords

Constraints; Modeling; Model predictive control; Multivariable systems; Process identification; Process testing

Introduction

Model predictive control (MPC) refer to a class of control algorithms that explicitly incorporate a process model for predicting the future response of a plant and relies on optimization as the means of determining control action. At each sample interval, MPC computes a sequence of future plant input signals that optimize future plant behavior. Only the first of the future input sequence is applied to the plant, and the optimization is repeated at subsequent sample intervals.

MPC provides an integrated solution for controlling non-square systems with complex dynamics, interacting variables, and constraints. MPC has become a standard in the continuous process industries, particularly in refining and chemicals, where it has been widely applied for over 25 years. In most commercial MPC products, an embedded steady-state optimizer is cascaded to the MPC controller. The MPC steady-state optimizer determines feasible, optimal settling values of the manipulated and controlled variables. The MPC controller then optimizes the dynamic path to optimal steady-state values.

The scope of an MPC application may include a unit operation such as a distillation column or reactor, or a larger scope such as multiple distillation columns, or a scope that combines reaction and separation sections of a plant in one controller. MPC is positioned in the control and decision hierarchy of a processing facility as shown in Fig. 1. The variables associated with MPC consist of: manipulated variables (MVs), controlled variables (CVs), and disturbance variables (DVs).


Industrial MPC of Continuous Processes, Fig. 1
Industrial control and decision hierarchy

CVs include variables normally controlled at a fixed value such as a product impurity and as well as those considered constraints, for example limits related to capacity or safety that may only be sometimes active. DVs are measurements that are treated as feedforward variables in MPC. The manipulated variables are typically setpoints of underlying PID controllers, but may also include valve position signals. Most of the targets and limits are local to the MPC, but others come directly from real-time optimization (if present), or indirectly from planning/scheduling, which are normally translated to the MPC in an open-loop manner by the operations personnel.

Linear and nonlinear model forms are found in industrial MPC applications; however, the majority of the applications continue to rely on a linear model, identified from data generated from a dedicated plant test. Nonlinearities that primarily affect system gains are often adequately controlled with linear MPC through gain scheduling or by applying linearizing static transformations. Nonlinear MPC applications tend to be reserved for those applications where nonlinearities are present in both system gains and dynamic responses and the controller must operate at significantly different targets.

Origins and History

MPC has its origins in the process industries in the 1970s. The year 1978 marked the first published description of predictive control under the name IDCOM, an acronym for Identification and Command (Richalet et al. 1978). A short time later, Cutler and Ramaker (1979) published a predictive control algorithm under the name Dynamic Matrix Control (DMC). Both approaches had been applied industrially for several years before the first publications appeared. These predictive control approaches targeted the more difficult industrial control problems that could not be adequately handled with other methods, either with conventional PID control or with advanced regulatory control (ARC) techniques that rely on single-loop controllers augmented with overrides, feedforwards/decouplers, and custom logic.

The basic idea behind the predictive control approach is shown in Fig. 2 for the case of a single input single output, stable system. Future predictions of inputs out outputs are denoted with the hat symbol and shown as dashes; double indexes, $t|k$, indicate future values at time t based on information up to and including time k. The optimization problem is to bring future predicted outputs $(\hat{y}_{k|k+1}, \ldots, \hat{y}_{k|k+P})$ close to a desired trajectory over a prediction horizon,

P, by means of a future sequence of inputs $(\hat{u}_{k|k}, \ldots, \hat{u}_{k|k+M-1})$ calculated over a control horizon M. The trajectory may be a constant setpoint. In the general case, the optimization is performed subject to constraints that may be imposed on future inputs and outputs. Only the first of the future moves is implemented and the optimization is repeated at the next time instant. Feedback, which accounts for unmeasured disturbances *and* model error, is incorporated by shifting all future output predictions, prior to the optimization, based on the difference between the output measurement y_k and the previous prediction $\hat{y}_{k|k-1}$, denoted by $d_{k|k}$ (i.e., the prediction error at time instant k). Future predicted values of the outputs depend on both past *and* future values inputs. If no future input changes are made (at time k or after), the model can be used to calculate the future "free" output response, $y_{t:k}^0$, which will ultimately settle at a new steady-state value based on the settling time (or time to steady state of the model, T_{ss}). For the unconstrained case, it is straightforward to show that the optimal result is a linear control law that depends only on the error between the desired trajectory and the free output response.

The predictive approach seemed to contrast with the state-space optimal control method of the time, the linear quadratic regulator (LQR). Later research exposed the similarities to LQR

Industrial MPC of Continuous Processes, Fig. 2 Predictive control approach
and also Internal Model Control (IMC) (Garcia and Morari 1982), although these techniques did not solve an online optimization problem. Optimization-based control approaches became feasible for industrial applications due to (1) the slower sampling requirements of most industrial control problems (on the order of minutes) and the hierarchical implementations in which MPC provides setpoints to lower level PID controllers which execute on a much faster sample time (on the order of seconds or faster).

Although the basic ideas behind MPC remain, industrial MPC technology has changed considerably since the first formulations in the late 1970s. Qin and Badgwell (2003) describe the enhancements to MPC technology that occurred over the next 20 plus years until the late 1990s. Enhancements since that time are highlighted in Darby and Nikolaou (2012). These improvements to MPC reflect increases in computer processing capability and additional requirements of industry, which have led to increased functionality and tools/techniques to simplify implementation. A summary of the significant enhancements that have been made to industrial MPC is highlighted below.

Constraints: Posing input and output constraints as linear inequalities, expressed as a function of the future input sequence (Garcia and Morshedi 1986), and solved by a standard quadratic program or an iterative scheme which approximates one.

Two-Stage Formulations: Limitations of a single objective function led to two-stage formulations to handle MV degrees of freedom (constraint pushing) and steady-state optimization via a linear program (LP).

Integrators. In their native form, impulse and step response models can be applied only to stable systems (in which the impulse response model coefficients approach zero). Extension to handle integrating variables included embedding a model of the difference of the integrating signal or integrating a fraction of the current prediction error into the future (implying an increasing $\left|d_{k+j|k}\right|$ for $j \geq 1$ in Fig. 2). The desired value of an integrator at steady state (e.g., zero slope) has been incorporated into two-stage formulations (see, e.g., Lee and Xiao 2000).

State Space Models. The first state space formulation of MPC, which was introduced in the late 1980s (Marquis and Broustail 1988) allowed MPC to be extended to integrating *and* unstable processes. It also made use of the Kalman filter which provided additional capability to estimate plant states and unmeasured disturbances. Later, a state space MPC offering was developed based on an infinite horizon (for both control and prediction) (Froisy 2006). These state space approaches provided a connection back to unconstrained LQR theory.

Nonlinear MPC. The first applications of nonlinear MPC, which appeared in the 1990s, were based on neural net models. In these approaches, a linear dynamic model was combined with a neural net model that accounted for static nonlinearity (Demoro et al. 1997; Zhao et al. 2001).

The late 1990s saw the introduction of an industrial nonlinear MPC based on first principle models derived from differential mass and energy balances and reaction kinetic expressions, expressed in differential algebraic equation (DAE) form (Young et al. 2002).

A process where nonlinear MPC is routinely applied is polymer manufacturing.

Identification Techniques. Multivariable prediction error techniques are now routinely used. More recently, industrial application of subspace identification methods has appeared, following the development of these algorithms in the 1990s. Subspace methods incorporate the correlation of output measurements in the identification of a multivariable state space model, which can be used directly in a state space MPC or converted to an impulse or step response model based MPC.

Testing Methods. The 1990s saw increased use of automatic testing methods to generate data for (linear) dynamic model identification using uncorrelated binary signals. Since the 2000, closed-loop testing methods have received considerable attention.

The motivation for closed-loop testing is to reduce implementation time and/or effort of the initial implementation as well as the ongoing need to re-identify the model of an industrial application in light of processes changes. These closed-loop testing methods, which require a preliminary or existing model, utilize uncorrelated dither signals either introduced as biases to the controller MVs or injected through the steady-state LP or QP, where additional logic or optimization of the test protocol may be performed (Kalafatis et al. 2006; MacArthur and Zhan 2007; Zhu et al. 2012).

Mathematical Formulation

While there are differences in how the MPC problem is formulated and solved, the following general form captures most of the MPC products (Qin and Badgwell 2003), although not all terms may be present in a given product:

$$
\min_{\Delta \mathcal{U}}
\begin{bmatrix}
\sum_{j=1}^{P} \left\| \hat{\mathbf{y}}_{k+j|k} - \mathbf{y}_{k+j|k}^{ref} \right\|_{\mathbf{Q}_j}^2 + \sum_{j=1}^{P} \left\| \mathbf{s}_{k+j|k} \right\|_{\mathbf{T}_j}^2 \\
\sum_{j=1}^{M-1} \left\| \hat{\mathbf{u}}_{k+j|k} - \mathbf{u}^{ss} \right\|_{\mathbf{R}_j}^2 + \sum_{j=1}^{M-1} \left\| \Delta \mathbf{u}_{k+j|k} \right\|_{\mathbf{S}_j}^2
\end{bmatrix}
\tag{1}
$$

subject to:

$$
\left.
\begin{aligned}
\hat{\mathbf{x}}_{k+j|k} &= \mathbf{f}(\hat{\mathbf{x}}_{k+j-1|k}, \hat{\mathbf{u}}_{k+j-1|k}), \quad j = 1, \dots P \\
\hat{\mathbf{y}}_{k+j|k} &= \mathbf{g}(\hat{\mathbf{x}}_{k+j|k}, \hat{\mathbf{u}}_{k+j|k}), \quad j = 1, \dots P
\end{aligned}
\right\} \text{ Model equations}
$$

$$
\left.
\begin{aligned}
\mathbf{y}^{\min} - \mathbf{s}_j &\le \hat{\mathbf{y}}_{k+j|k} \le \mathbf{y}^{\max} + \mathbf{s}_j, \quad j = 1, \dots, P \\
\mathbf{s}_j &\ge 0, \quad j = 1, \dots P
\end{aligned}
\right\} \text{ Output constraints/slacks}
$$

$$
\left.
\begin{aligned}
\mathbf{u}^{\min} &\le \hat{\mathbf{u}}_{k+j|k} \le \mathbf{u}^{\max}, \quad j = 0, \dots M-1 \\
-\Delta \mathbf{u}^{\min} &\le \Delta \mathbf{u}_{k+j|k} \le \Delta \mathbf{u}^{\max}, \quad j = 0, \dots M-1
\end{aligned}
\right\} \text{ Input constraints}
$$

where the minimization is performed over the future sequence of inputs $\mathcal{U} \triangleq \hat{\mathbf{u}}_{k|k}, \hat{\mathbf{u}}_{k+1|k}, \dots, \hat{\mathbf{u}}_{k+M-1|k}$. The four terms in the objective function represent conflicting quadratic penalties ($\|\mathbf{x}\|_{\mathbf{A}}^2 \triangleq \mathbf{x}^T \mathbf{A}\mathbf{x}$); the penalty matrices are most always diagonal. The first term penalizes the error relative to a desired reference trajectory (cf. Fig. 2) originating at $\hat{\mathbf{y}}_{k|k}$ and terminating at a desired steady-state, $\mathbf{y}^{ss}$; the second term penalizes output constraint violations over the prediction horizon (constraint softening); the third term penalizes inputs deviations from a desired steady-state, either manually specified or calculated. The fourth term penalizes input changes as a means of trading off output tracking and input movement (move suppression).

The above formulation applies to both linear and nonlinear MPC. For linear MPCs, except for state space formulations, there are no state

equations and the outputs in the dynamic model are a function of only past inputs, such as with the finite step response model.

When a steady-state optimizer is present in the MPC, it provides the steady-state targets for $\mathbf{u}^{ss}$ (in the third quadratic term) and $\mathbf{y}^{ss}$ (in the output reference trajectory). Consider the case of linear MPC with LP as the steady-state optimizer. The LP is typically formulated as

$$
\min_{\Delta \mathbf{u}^{ss}} \mathbf{c}_u^T \Delta \mathbf{u}^{ss} + \mathbf{c}_y^T \Delta \mathbf{y}^{ss} + \mathbf{q}_+^T \mathbf{s}^+ + \mathbf{q}_-^T \mathbf{s}^-
$$

subject to:

$$
\left.
\begin{aligned}
\Delta \mathbf{y}^{ss} &= \mathbf{G}^{ss} \Delta \mathbf{u}^{ss} \\
\mathbf{u}^{ss} &= \mathbf{u}_{k-1} + \Delta \mathbf{u}^{ss} \\
\mathbf{y}^{ss} &= \mathbf{y}_{k+T_{ss}|k}^0 + \Delta \mathbf{y}^{ss}
\end{aligned}
\right\} \text{ Model equations}
$$

$$\left. \mathbf{y}^{\min} - \mathbf{s}^- \le \mathbf{y}^{ss} \le \mathbf{y}^{\max} + \mathbf{s}^+ \right\} \text{ Output constraints}$$

$$\left. \begin{array}{c} \mathbf{u}^{\min} \le \mathbf{u}^{ss} \le \mathbf{u}^{\max} \\[6pt] -M\Delta\mathbf{u}^{\max} \le \mathbf{u}^{ss} \le M\Delta\mathbf{u}^{\max} \end{array} \right\} \text{ Input constraints}$$

$\mathbf{G}^{ss}$ is formed from the gains of the linear dynamic model. Deviations outside minimum and maximum output limits ($\mathbf{s}^-$ and $\mathbf{s}^+$, respectively) are penalized, which provide constraint softening in the event all outputs cannot be simultaneously controlled within limits. The weighting in $\mathbf{q}_-$ and $\mathbf{q}_+$ determine the relative priorities of the output constraints. The input constraints, expressed in terms of $\Delta\mathbf{u}^{\max}$, prevent targets from being passed to the dynamic optimization that cannot be achieved. The resulting solution – $\mathbf{u}^{ss}$ and $\mathbf{y}^{ss}$ – provides a consistent, achievable steady-state for the dynamic MPC controller. Notice that for inputs, the steady-state delta is applied to the current value and, for outputs, the steady-state delta is applied to the steady-state prediction of the output without future moves, after correcting for the current model error (cf. Fig. 2). If a real-time optimizer is present, its outputs, which may be targets for CVs and/or MVs, are passed to the MPC steady-state optimizer and considered with other objectives but at lower weights or priorities.

Some additional differences or features found in industrial MPCs include:

1-Norm formulations where absolute deviations, instead of quadratic deviations, are penalized.

Use of zone trajectories or "funnels" with small or no penalty applied if predictions remain within the specified zone boundaries.

Use of a minimum movement criterion in either the dynamic or steady-state optimizations, which only lead to MV movement when CV predictions go outside specified limits. This can provide controller robustness to modeling errors.

Multiobjective formulations which solve a series of QP or LP problems instead of a single one, and can be applied to the dynamic or steady-state optimizations. In these formulations, higher priority objectives are solved first, followed by lesser priority objectives with the solution of the higher priority objectives

becoming equality constraints in subsequent optimizations (Maciejowski 2002).

MPC Design

Key design decision for a given application are the number of MPC controllers and the selection of the MVs, DVs, and CVs for each controller; however, design decisions are not limited to just the MPC layer. The design problem is one of deciding on the best overall structure for the MPC(s) *and* the regulatory controls, given the control objectives, expected constraints, qualitative knowledge of the expected disturbances, and robustness considerations. It may be that existing measurements are insufficient and additional sensors may be required. In addition, a measurement many not be updated on a time interval consistent with acceptable dynamic control, for example, laboratory measurements and process composition analyzers. In this case, a soft sensor, or inferential estimator, may need to be developed from temperature and pressure measurements.

MPC is frequently applied to a major plant unit, with the MVs selected based on their sensitivity to key unit CVs and plant economics. Decisions regarding the number and size of the MPCs for a given application depend on plant objectives, (expected) constraints, and also designer preferences. When the objective is to minimize energy consumption based on fixed or specified feed rate, multiple smaller controllers can be used. In this situation, controllers are normally designed based on the grouping of MVs with the largest effect on the identified CVs, often leading to MPCs designed for individual sections of equipment, such as reactors and distillation columns. When the objective is to maximize feed (or certain products), larger controllers are normally designed, especially if there are multiple constraints that can limit plant throughput. The MPC steady-state LP or QP is ideally suited to solving the throughput maximization problem by utilizing all available MVs. The location of the most limiting constraints can impact the number of MPCs. If the major constraints are near the front-end of the plant, one MPC can be designed

which connects these constraints with key MVs such as feed rates, and other MPCs designed for the rest of the plant. If the major constraints are located near the back of the plant, then a single MPC is normally considered; alternatively, an MPC cascade could be considered, although this is not a common practice across the industry (and often requires customization).

The feed maximization objective is a major reason why MPCs have become larger with the advances in computer processing capability. However, there is generally a higher requirement on model consistency for larger controllers due do the increased number of possible constraint sets against which the MPC can operate. A larger controller can also be harder to implement and understand. This is a reason why some practitioners prefer implementing smaller MPCs at the potential loss of benefits.

MPC Practice

An MPC project is typically implemented in the following sequence:
Pretest and preliminary MPC design
Plant testing
Model and controller development
Commissioning
These tasks apply whether the MPC is linear or nonlinear, but with some differences, primarily model development and in plant testing. In nonlinear MPC, key decisions are related to the model form and level of rigor. Note that with a fundamental model, lower level PID loops must be included in the model, if the dynamics are significant; this is in contrast to empirical modeling, where the dynamics of the PID loops are embedded in the plant responses. A fundamental model will typically require less plant testing and make use of historical operating data to fit certain model parameters such as heat transfer coefficients and reaction constants. Historical data and/or data from a validated nonlinear static model can also be used to develop nonlinear static models (e.g., neural net) to combine with empirical dynamic models. As mentioned earlier, most industrial applications continue to rely on

empirical linear dynamic models, fit to data from a dedicated plant test. This will be the basis in the following discussion.

In the pretest phase of work, the key activity is one of determining the base level regulatory controls for MPC, tuning of these controls, and determining if the current plant instrumentation is adequate. It is common to retune a significant number of PID loops, with significant benefits often resulting from this step alone.

A range of testing approaches are used in plant testing for linear MPC, including both manual and automatic (computer-generated) test signal designs, most often in open loop but, increasingly, in closed loop. Most input testing continues to be based on uncorrelated signals, implemented either manually or from computer-generated random sequences. Model accuracy requirements dictate accuracy across a range of frequencies which is achieved by varying the duration of the steps. Model identification runs are made through out the course of a test to determine when model accuracy is sufficient and a test can be stopped.

In the next phase of work, modeling of the plant is performed. This includes constructing the overall MPC model from individual identification runs; for example, deciding which models are significant and judging the models characteristics (dead times, inverse response settling time, gains) based on engineering/process and a priori knowledge. An important step is analyzing, and adjusting if necessary, the gains of the constructed model to insure the models gains satisfy mass balances and gain ratios do not result in fictitious degrees of freedom (due to model errors) that the steady-state optimizer could exploit. Also included is the development of any required inferentials or soft sensors, typically based on multivariate regression techniques such as principal component regression (PCR), principal component analysis (PCA) and partial least squares (PLS), or sometimes based on a fundamental model.

During controller development, initial controller tuning is performed. This relates to establishing criteria for utilizing available degrees of freedom and setting control variable priorities. In addition, initial tuning values are established for

the dynamic control. Steady state responses corresponding to expected constraint scenarios are analyzed to determine if the controller behaves as expected, especially with respect to the steady-state changes in the manipulated variables.

Commissioning involves testing and tuning the controller against different constraint sets. It is not unusual to modify or revisit model decisions made earlier. In the worst case, control performance may be deemed unacceptable and the control engineer is forced to revisit earlier decisions such as the base level regulatory strategy or plant model quality, which would require re-testing and re-identification of portions of the plant model. The main commissioning effort typically takes place over a two to three week period, but can vary based on the size and model density of the controller. In reality, commissioning, or more accurately, controller maintenance, is an ongoing activity. It is important that the operating company have in-house expertise that can be used to answer questions ("why is the controller doing that?"), troubleshoot, and modify the controller to reflect new operating modes and constraint sets.

Future Directions

Likely future developments are expected to follow extensions of current approaches. Due to the success in automatic, closed-loop testing, one possibility is extending it to "dual" or "joint" control, where control and identification objectives are combined and allow the user to select how much the control (e.g., output variance) can be affected by test perturbation signals. Another is in formulating the plant test as a DOE 8 (design of experiments) optimization problem that could, for example, target specific models or model parameters. In the identification area, extensions have started to appear which allow constraints to be imposed, for example, on dead-times or gains, thus allowing a priori knowledge to be used. Another important area that has seen recent emphasis, and which more development can be expected, is in monitoring and diagnosis, for example, detecting which submodels of MPC have become inaccurate and require re-identification.

As mentioned earlier, one of the advantages of state-space modeling is the inherent flexibility to model unmeasured disturbances (i.e., $d_{k+j|j}$, cf. Fig. 2); however, these have not found widespread use in industry. A useful enhancement would be a framework for developing and implementing improved estimators in a convenient and transparent manner, that would be applicable to traditional FIR- and FSR- based MPCs.

In the area of nonlinear control, the use of hybrid modeling approaches has increased, for example, integrating known fundamental model relationships with neural net or linear time-varying dynamic models. The motivation is in reducing complexity and controller execution times. The use of hybrid techniques can be expected to further increase, especially if nonlinear control is to be applied more broadly to larger control problems. Even in situations where control with linear MPC is adequate, there may be benefits from the use of hybrid or fundamental models, even if the models are not directly used in the control calculation. The resulting model could be used offline in model development or online to update the linear MPC model. Benefits would come from reduced plant testing and in ensuring model consistency. In the longer term, one can foresee a more general modeling and control environment where the user would not have to be concerned with the distinction between linear and nonlinear models and would be able to easily incorporate known relationships into the controller model.

An area that has not received significant attention, but is suggested as an area worth pursuing concerns MPC cascades. Most of the applications and research are based on a single MPC or multiply distributed MPCs. An MPC cascade would permit the lower MPC to run at a faster time period and allow the user to decide which degrees of freedom are to be used for higher level objectives, such as feed maximization.

Information and Communication Complexity of Networked Control Systems

Serdar Yüksel
Department of Mathematics and Statistics,
Queen's University, Kingston, ON, Canada

Abstract

Information and communication complexity of
a networked control system identifies the minimum amount of information exchange needed
between the decision makers (such as encoders,
controllers, and actuators) to achieve a certain
objective, which may be in terms of reaching a
target state or achieving a given cost threshold.
This formulation does not impose any constraints
on the computational requirements to perform the
communication or control. Both stochastic and
deterministic formulations are considered.

Keywords

Communication complexity; Information theory;
Networked control

Introduction

Consider a dynamic team problem with L control
stations (these will be referred to as decision
makers and denoted by DMs) under the following
dynamics and measurement equations:

$$x_{t+1} = f_t(x_t, u_t^1, \ldots, u_t^L, w_t), \qquad t = 0, 1, \cdots \tag{1}$$

$$y_t^i = g_t^i(x_t, u_{t-1}^1, \ldots, u_{t-1}^L; v_t^i), \tag{2}$$

**Information and
Communication
Complexity of
Networked Control
Systems, Fig. 1** A
decentralized networked
control system with
information exchange
between decision makers
where $i \in \{1, 2, \ldots, L\} =: \mathcal{L}$ and $x_0, w_{[0,T-1]}$, $v_{[0,T-1]}^i$ are mutually independent random variables with specified probability distributions. Here, we use the notation $w_{[0,t]} := \{w_s, 0 \leq s \leq t\}$.

The DMs are allowed to exchange limited information: see Fig. 1. The information exchange is facilitated by an encoding protocol $\mathcal{E}$ which is a collection of admissible encoding functions described as follows. Let the information available to DM i at time t be

$$\mathcal{I}_t^i = \{y_{[1,t]}^i, u_{[1,t-1]}^i, z_{[0,t]}^{i,j}, z_{[0,t]}^{j,i}, j \in \mathcal{L}\},$$

where $z_t^{i,j}$ takes values in $\mathcal{Z}_t^{i,j}$ and is the information variable transmitted from DM i to DM j at time t generated with

$$\mathbf{z}_t^i = \{z_t^{i,j}, j \in \mathcal{L}\} = \mathcal{E}_t^i(\mathcal{I}_{t-1}^i, u_{t-1}^i, y_t^i), \quad (3)$$

and for $t = 0$, $\mathbf{z}_0^i = \{z_0^{i,j}, j \in \mathcal{L}\} = \mathcal{E}_0^i(y_0^i)$. The control actions are generated with

$$u_t^i = \gamma_t^i(\mathcal{I}_t^i),$$

for all DMs. Define $\log_2(|\mathcal{Z}_t^{i,j}|)$ to be the *communication rate from DM i to DM j at time t* and $\mathcal{R}(\mathbf{z}_{[0,T-1]}) = \sum_{t=0}^{T-1} \sum_{i,j \in \mathcal{L}} \log_2(|\mathcal{Z}_t^{i,j}|)$ to be the *(total) communication rate*. The minimum (total) communication rate over all coding and control policies subject to a design objective

is called the *communication complexity* for this objective.

The above is a fixed-rate formulation for communication complexity, since for any two coder outputs, a fixed number of bits is used at any given time. One could also use variable-rate formulations. The variable-rate formulation exploits the probabilistic distribution of the system variables: see Cover and Thomas (1991).

Communication Complexity for Decentralized Dynamic Optimization

Let $\underline{\mathcal{E}}^i = \{\mathcal{E}_t^i, t \geq 0\}$ and $\underline{\gamma}^i = \{\gamma_t^i, t \geq 0\}$. Under a team-encoding policy $\underline{\mathcal{E}} = \{\underline{\mathcal{E}}^1, \underline{\mathcal{E}}^2, \ldots, \underline{\mathcal{E}}^L\}$, and a team-control policy $\underline{\gamma} = \{\underline{\gamma}^1, \underline{\gamma}^2, \ldots, \underline{\gamma}^L\}$, let the induced cost be

$$E^{\underline{\gamma}, \underline{\mathcal{E}}}[\sum_{t=0}^{T-1} c(x_t, u_t^1, u_t^2, \cdots, u_t^L)]. \quad (4)$$

In networked control, the goal is to minimize (4) over all coding and control policies subject to information constraints in the system. Let $\mathbf{u}_t = \{u_t^1, u_t^2, \cdots, u_t^L\}$. The following definition and example are from Yüksel and Başar (2013).

Definition 1 Given a decentralized control problem as above, *team cost-rate function* $C : \mathbb{R} \to \mathbb{R}$ is

$$C(R) := \inf_{\underline{\gamma}, \underline{\mathcal{E}}} \left\{ E^{\underline{\gamma}, \underline{\mathcal{E}}}[\sum_{t=0}^{T-1} c(x_t, \mathbf{u}_t)] : \right.$$

$$\left. \frac{1}{T}\mathcal{R}(\mathbf{z}_{[0,T-1]}) \leq R \right\}.$$

We can define a dual function.

Definition 2 Given a decentralized control problem as above, *team rate-cost function* $R : \mathbb{R} \to \mathbb{R}$ is

$$R(C) := \inf_{\underline{\gamma}, \underline{\mathcal{E}}} \left\{ \frac{1}{T}\mathcal{R}(\mathbf{z}_{[0,T-1]}) : \right.$$

$$\left. E^{\underline{\gamma}, \underline{\mathcal{E}}}[\sum_{t=0}^{T-1} c(x_t, \mathbf{u}_t)] \leq C \right\}.$$

The formulation here can be adjusted to include sequential (iterative) information exchange given a fixed ordering of actions, as opposed to a simultaneous (parallel) information exchange at any given time t. That is, instead of (3), we may have

$$\mathbf{z}_t^i = \{z_t^{i,j}, j \in \{1, 2, \ldots, L\}\}$$
$$= \mathcal{E}_t^i(\mathcal{I}_{t-1}^i, u_{t-1}^i, y_t^i, \{z_t^{k,i}, k < i\}). \quad (5)$$

Both to make the discussion more explicit and to show that a sequential (iterative) communication protocol may perform strictly better than an optimal parallel communication protocol given a total rate constraint, we state the following example: Consider the following setup with two DMs. Let x^1, x^2, p be uniformly distributed binary random variables, DM i have access to y^i, $i = 1, 2$, and

$$x = (p, x^1, x^2), \qquad y^1 = p, \qquad y^2 = (x^1, x^2),$$

and the cost function be

$$c(x, u^1, u^2) = 1_{\{p=0\}}c(x^1, u^1, u^2)$$
$$+ 1_{\{p=1\}}c(x^2, u^1, u^2),$$

with

$$c(s, u^1, u^2) = (s - u^1)^2 + (s - u^2)^2.$$

Suppose that we wish to compute the minimum expected cost subject to a total rate of 2 bits that can be exchanged. Under a sequential scheme, if we allow DM 1 to encode y^1 to DM 2 with 1 bit, then a cost of 0 is achieved since DM 2 knows the relevant information that needs to be transmitted to DM 1, again with 1 bit: If $p = 0$, x^1 is the relevant random variable with an optimal policy $u^1 = u^2 = x^1$, and if $p = 1$, x^2 is relevant with an optimal policy $u^1 = u^2 = x^2$, and a cost of 0 is achieved. However, if the information exchange is parallel, then DM 2 does not know which state is the relevant one, and it can be shown that a cost of 0 cannot be achieved under any policy.

The formulation in Definition 1 can also be adjusted to allow for multiple rounds of communication per time stage. Having multiple rounds can enhance the performance for a class of team problems while keeping the total rate constant.

Communication Complexity in Decentralized Computation

Yao (1979) initiated the research on communication complexity in distributed computation. This may be viewed as a special case of the setting considered earlier but with finite spaces and in a deterministic and an error-free context: Consider two decision makers (DMs) who have access to local variables $x \in \{0,1\}^n$, $y \in \{0,1\}^n$. Given a function f of variables (x, y), what is the maximum (over all input variables x, y) of the minimum amount of information exchange needed for at least one agent to compute the value of the function? Let $s(x, y) = \{m_1, m_2, \cdots, m_t\}$ be the communication symbols exchanged on input (x, y) during the execution of a communication protocol. Let m_i denote the ith binary message symbol with $|m_i|$ bits. The communication complexity for such a setup is defined as

$$R(f) = \min_{\underline{\gamma}, \underline{\mathcal{E}}} \max_{(x,y) \in \{0,1\}^n \times \{0,1\}^n} |s(x, y)|, \quad (6)$$

where $|s(x, y)| = \sum_{i=1}^{t} |m_i|$ and $\underline{\mathcal{E}}$ is a protocol which dictates the iterative encoding functions as in (5) and $\underline{\gamma}$ is a decision policy.

For such problems, obtaining *good* lower bounds is in general challenging. One lower bound for such problems is obtained through the following reasoning: A subset of the form $A \times B$, where A and B are subsets of $\{0, 1\}^n$, is called an f-*monochromatic* rectangle if for every $x \in A, y \in B$, $f(x, y)$ is the same. It can be shown that given any finite message sequence $\{m_1, m_2, \cdots, m_t\}$, the set $\{(x, y) : s(x, y) = \{m_1, m_2, \cdots, m_t\}\}$ is an f-*monochromatic* rectangle. Hence, to minimize the number of messages, one needs to minimize the number of f-monochromatic rectangles which has led to research in this direction. Upper bounds are typically obtained by explicit constructions. For a comprehensive review, see Kushilevitz and Nisan (2006).

For control systems, the discussion takes further aspects into account including a design objective, system dynamics, and the uncertainty in the system variables.

Communication Complexity in Reach Control

Wong (2009) defines the communication complexity in networked control as follows: Consider a design specification where two DMs wish to steer the state of a dynamical system in finite time. This can be viewed as a setting in (1)–(2) with 4 DMs, where there is iterative communication between a sensor and a DM, and there is no stochastic noise in the system. Given a set of initial states $x_0 \in \mathcal{X}_0$, and finite sets of objective choices for each DM ($\mathcal{A}$ for DM 1, $\mathcal{B}$ for DM 2), the goal is to ensure that (i) there exists a finite time where both DMs know the final state of the system, (ii) the final state satisfies the choices of the DMs, and (iii) the finite time (when the objective is satisfied) is known by the DMs.

The communication complexity for such a system is defined as the infimum over all protocols of the supremum over the triple of initial states, and choices of the DMs, such that the above is satisfied. That is,

$$R(\mathcal{X}_0, \mathcal{A}, \mathcal{B}) = \inf_{\gamma, \underline{\mathcal{E}}} \sup_{\alpha, \beta, x_0} R(\gamma, \underline{\mathcal{E}}, \alpha, \beta, x_0),$$

where $R(\gamma, \underline{\mathcal{E}}, \alpha, \beta, x_0)$ denotes the communication rate under the control and coding functions $\gamma, \underline{\mathcal{E}}$, which satisfies the objectives given by the choices α, β and initial condition x_0.

Wong obtains a cut-set type lower bound: Given a fixed initial state, a lower bound is given by $2D(f)$, where f is a function of the objective choices and $D(f)$ is a variation of $R(f)$ introduced in (6) with the additional property that both DMs know f at the end of the protocol. An upper bound is established by the exchange of the initial states and objective functions also taking into account signaling, that is, the communication through control actions, which is discussed further below in the context of stabilization. Wong and Baillieul (2012) consider a detailed analysis for a real-valued bilinear controlled decentralized system.

Connections with Information Theory

Information theory literature has made significant contributions to such problems. An information theoretic setup typically entails settings where an unboundedly large sequence of messages are encoded and functions of which are to be computed. Such a setting is not applicable in a real-time setting but is very useful for obtaining performance bounds (i.e., good lower bounds on complexity) which can at certain instances be achievable even in a real-time setting. That is, instead of a single realization of random variables in the setup of (1)–(2), the average performance for a large number of independent realizations/copies for such problems is typically considered.

In such a context, Definitions 1 and 2 can be adjusted so that the communication complexity is computed by mutual information (Cover and Thomas 1991). Replacing the fixed-rate or variable-rate (entropy) constraint in Definition 1 with a mutual information constraint leads to convexity properties for $C(R)$ and $R(C)$. Such an information theoretic formulation can provide useful lower bounds and desirable analytical properties.

We note here the interesting discussion between decentralized computation and

communication provided by Orlitsky and Roche (2001) as well as by Witsenhausen (1976) where a *probability-free* construction is considered and a *zero-error (non-asymptotic and error-free)* computation is considered in the same spirit as in Yao (1979).

Such decentralized computation problems can be viewed as multiterminal source coding problems with a cost function aligned with the computation objective. Ma and Ishwar (2011) and Gamal and Kim (2012) provide a comprehensive treatment and review of information exchange requirements for computing. Essential in such constructions is the method of *binning*, which is a key tool in distributed source coding problems. Binning efficiently designates the enumeration of symbols (which can be confused in the absence of coding) given the relevant information at a receiver DM.

Such problems involve interactive communications as well as multiterminal coding problems. As mentioned earlier, it is also important to point out that multi-round protocols typically reduce the average rate requirements.

Communication Complexity in Decentralized Stabilization

An important relevant setting of reach control is where the target final state is the zero vector: The system is to be stabilized. Consider the following special case of (1)–(2) for an LTI system:

$$x_{t+1} = Ax_t + \sum_{j=1}^{L} B^j u_t^j,$$

$$y_t^i = C^i x_t \ t = 0, 1, \ldots \qquad (7)$$

where $i \in \mathcal{L}$, and it is assumed that the joint system is stabilizable and detectable, but the individual pairs (A, B^i) may not be stabilizable or (A, C^i) may not be detectable. Here, $x_t \in \mathbb{R}^n$ is the state, $u_t^i \in \mathbb{R}^{m_i}$ is the control applied by station i, and $y_t^i \in \mathbb{R}^{p_i}$ is the observation available at station i, all at time t. The initial state x_0 is generated according to a probability
Information and Communication Complexity of Networked Control Systems, Fig. 2 Decentralized stabilization with multiple controllers

distribution supported on a compact set $\mathcal{X}_0 \subset \mathbb{R}^n$. We denote controllable and unobservable subspaces at station i by K^i and N^i and refer to the subspace orthogonal to N^i as the observable subspace at the ith station, denoted by O^i. The information available to station i at time t is $I_t^i = \{y_{[0,t]}^i, u_{[0,t-1]}^i\}$. For such a system (see Fig. 2), it is possible for the controllers to communicate through the plant with the process known as *signaling* which can be used for communication of mode information among the decision makers. Denote by $i \rightarrow j$ the property that DM i can signal to DM j. This holds if and only if $C^j (A)^l B^i \neq 0$, for at least one l, $1 \leq l \leq n$. A directed graph $\mathcal{G}$ among the L stations can be constructed through such a communication relationship.

Suppose that A is such that in its Jordan form, where each Jordan block admits distinct real eigenvalues. Then, a lower bound on the communication complexity (per time stage) for stabilizability is given by $\sum_{|\lambda_i|>1} \eta_{M_i} \log_2(|\lambda_i|)$, where

$$\eta_{M_i} = \min_{l,m \in \{1,2,\ldots,L\}} \{d(l,m) + 1 : l \rightarrow m,$$

$$[x^i] \subset O^i \cup O^m, \quad [x^i] \subset K^m\},$$

with $d(l, m)$ denoting the graph distance (number of edges in a shortest path) between DM l and DM m in $\mathcal{G}$ and $[x_i]$ denoting the subspace spanned by x_i. Furthermore, there exist stabilizing coding and control policies whose sum rate is arbitrarily close to this bound. When different Jordan blocks may admit repeated and possibly complex eigenvalues, variations of the result above are applicable. In the special case where there is a centralized controller which receives information from multiple sensors (under stabilizability and joint detectability), even in the presence of noise, to achieve asymptotic stability, it suffices to have the average total rate be greater than $\sum_{|\lambda_i| > 1} \log_2(|\lambda_i|)$. The results above follow from Matveev and Savkin (2008) and Yüksel and Başar (2013). For the case with a single sensor, this result has been studied extensively in networked control (see the chapter on ▶ Quantized Control and Data Rate Constraints in the Encyclopedia).

Summary and Future Directions

In this text, we discussed the problem of communication complexity in networked control systems. Our analysis considered both cost minimization and controllability/reachability problems subject to information constraints. We also discussed the communication complexity in distributed computing as has been studied in the computer science community and provided a brief discussion on the information theoretic approaches for such problems together with structural results. There are many relevant open problems on structural results for optimal policies, explicit solutions, as well as nontrivial upper and lower bounds on the optimal performance.

Recommended Reading

The information exchange requirements for decentralized optimization depend also on the structural properties of the cost functional to be minimized. For a class of team problems, one might simply need to exchange a sufficient statistic needed for optimal solutions. For some problems, there may be no need for an exchange at all, if the sufficient statistics are already available, as in the case of *mean field equilibrium* problems when the number of decision makers is unbounded or very large for almost optimal solutions; see Huang et al. (2006) and Lasry and Lions (2007). In case there is no common probabilistic information, the problem considered becomes further involved. The consensus literature, under both Bayesian and non-Bayesian contexts, aims to achieve agreement on a class of system variables under information constraints: see, e.g., Tsitsiklis et al. (1986). Optimization under local interaction and sparsity constraints and various criteria have been investigated in a number of publications including Rotkowitz and Lall (2006). A review for the literature on norm-optimal control as well as optimal stochastic dynamic teams is provided in Mahajan et al. (2012). Tsitsiklis and Athans (1985) have observed that from a computational complexity viewpoint, obtaining optimal solutions for a class of such communication protocol design problems is non-tractable (NP-hard).

Even though obtaining explicit solutions for optimal coding and control results may be difficult, it is useful to obtain structural results on optimal coding and control policies since one can reduce the search space to a smaller class of functions. For dynamic team problems, these typically follow from the construction of a controlled Markov chain (see Walrand and Varaiya 1983) and applying tools from stochastic control theory which obtain structural results on optimal coding and control policies (see Nayyar et al. 2013).

Along these lines, for system (1)–(2), if the DMs can agree on a joint belief $P(x_t \in \cdot | I_t^i, i \in \mathcal{L})$ at every time stage, then the optimal cost that would be achieved under a centralized system could be attained (see Yüksel and Başar 2013). As a further important illustrative case, if the problem described in Definition 1 is for a real-time estimation problem for a Markov source, then the optimal causal fixed-rate coder minimizing any cost function uses only the last source symbol and the information at the controller's memory: see Witsenhausen (1979). We also note that the optimal design of information channels for optimization under information constraints is a non-convex problem; see Yüksel and Linder (2012) and Yüksel and Başar (2013) for a review of the literature and certain topological properties of the problem. We refer the reader to Nemirovsky and Yudin (1983) for a comprehensive resource on information complexity for optimization problems. A sequential setting with an information theoretic approach to the formulation of communication complexity has been considered in Raginsky and Rakhlin (2011). A formulation relevant to the one in Definition 1 has been considered in Teneketzis (1979) with mutual information constraints. Giridhar and Kumar (2006) discuss distributed computation for a class of symmetric functions under information constraints and present a comprehensive review.

Information Structures, the Witsenhausen Counterexample, and Communicating Using Actions

Pulkit Grover
Carnegie Mellon University, Pittsburgh, PA, USA

Abstract

The concept of "information structures" in decentralized control is a formalization of the notion of "who knows what and when do they know it." Even seemingly simple problems with simply stated information structures can be extremely hard to solve. Perhaps the simplest of such unsolved problem is the celebrated Witsenhausen counterexample, formulated by Hans Witsenhausen in 1968. This entry discusses how the information structure of the Witsenhausen counterexample makes it hard and how an information-theoretic approach, which explores the knowledge gradient due to a nonclassical information pattern, has helped obtain insights into the problem.

Keywords

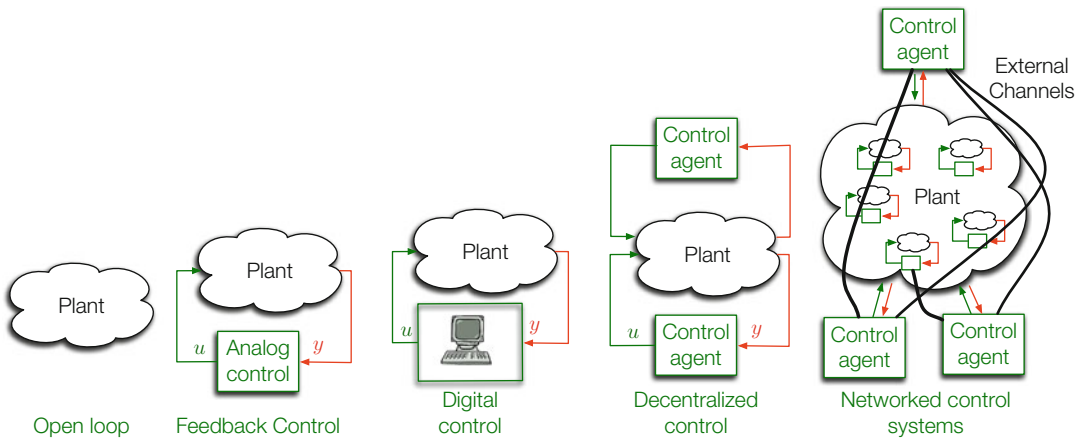
Decentralized control; Information theory; Implicit communication; Team decision theory

Introduction

Modern control systems often comprise of multiple decentralized control agents that interact over communication channels (Fig. 1). What characteristic distinguishes a centralized control problem from a decentralized one? One fundamental difference is a "knowledge gradient": agents in a decentralized team often observe, and hence know, different things. This observation leads to the idea of *information patterns* (Witsenhausen 1971), a formalization of the notion of "who

knows what and when do they know it" (Ho et al. 1978; Mitter and Sahai 1999).

The information pattern is said to be *classical* if all agents in the team receive the same information and have perfect recall (so they do not forget it). What is so special about classical information patterns? For these patterns, the presence of external communication links has no effect on the optimal costs! After all, what could the agents use the communication links for, when there is no knowledge gradient? More interesting, therefore, are the problems for which the information pattern is *non*classical. These problems sit at the intersection of communication and control: *communication between agents* can help reduce the knowledge differential that exists between them, helping them perform the *control* task. Intellectually and practically, the concept of nonclassical information patterns motivates a lot of formulations at the control-communication intersection. Many of these formulations – including some discussed in this Encyclopedia (e.g., ▸ Data Rate of Nonlinear Control Systems and Feedback Entropy; ▸ Information and Communication Complexity of Networked Control Systems ▸ Quantized Control and Data Rate Constraints; ▸ Networked Control Systems: Architecture and Stability Issues; and ▸ Networked Control Systems: Estimation and Control Over Lossy Networks) – intellectually ask the question: for a realistic channel that is constrained by noise, bandwidth, and speed, what is the optimal communication *and* control strategy?

One could ask the question of optimal control strategy even for decentralized control problems where no external channel is available to bridge this knowledge gradient. Why could these problems be of interest? First, these problems are limiting cases of control with communication constraints. Second, and perhaps more importantly, they bring out an interesting possibility that can allow the agents to "communicate," i.e., exchange information, *even when the external channel is absent*. It is possible to use control actions to *communicate* through changing the system state! We now introduce this form of communication using a simple toy example.


Information Structures, the Witsenhausen Counterexample, and Communicating Using Actions, Fig. 1 The evolution of control systems. Modern "net-worked control systems" (also called "cyber-physical systems") are decentralized and networked using communication channels

Communicating Using Actions: An Example

To gain intuition into when communication using actions could be useful, consider the inverted pendulum example shown in Fig. 2. The goal of the two agents is to bring the pendulum as close to the origin as possible. Both controllers have their strengths and weaknesses. The "weak" controller C_w has little energy, but has perfect state observations. On the other hand, the "blurry" controller C_b has infinite energy, but noisy observations. They act one after the other, and their goal is to move the pendulum close to the center from any initial state. The information structure of the problem is nonclassical: the C_w, but not C_b, knows the initial state of the pendulum, and C_w does not know the precise (noisy) observation of C_b using which C_b takes actions.

A possible strategy: A little thought reveals an interesting strategy – the weak controller, having perfect observations, can move the state to the closest of some predecided points in space, effectively *quantizing* the state. If these quantization points are sufficiently far from each other, they can be estimated accurately (through the noise) by the blurry controller, which can then use its energy to push the pendulum all the way to zero. In this way, the weak controller expends little energy, but is able to "communicate" the state through the noise to the blurry controller, by

Information Structures, the Witsenhausen Counterexample, and Communicating Using Actions, Fig. 2 Two controllers, with their respective strengths and weaknesses, attempting to bring an inverted pendulum close to the center. Also shown (using green "+" signs) are possible quantization points chosen by the controllers for a quantization-based control strategy

making it take values on a finite set. Once the blurry controller has received the state through the noise, it can use its infinite energy to push the state to zero.

The Witsenhausen Counterexample

The above two-controller inverted-pendulum example is, in fact, motivated by what is now known as "the Witsenhausen counterexample," formulated by Witsenhausen in 1968 (see Fig. 3).

$$x_0 \sim \mathcal{N}(0, \sigma_0^2)$$

$$\min \left\{ k^2 \mathbb{E}\left[u_w^2 \right] + \mathbb{E}\left[x_2^2 \right] \right\}$$
Information Structures, the Witsenhausen Counterexample, and Communicating Using Actions, Fig. 3 The Witsenhausen counterexample is a deceptively simple two-time-step two-controller decentralized control problem. The weak and the blurry controllers, C_w and C_b act in a sequential manner

Information Structures, the Witsenhausen Counterexample, and Communicating Using Actions, Fig. 4 The optimization solution of Baglietto et al. (1997) for $k^2 = 0.5$, $\sigma_0^2 = 5$. The information-theoretic strategy of "dirty-paper coding" Costa (1983) also yields the same curve (Grover and Sahai 2010)

In the counterexample, two controllers (denoted here by C_w for "weak" and C_b for "blurry") act one after the other in two time-steps to minimize a quadratic cost function. The system state is denoted by x_t, where t is the time index. u_w and u_b denote the inputs generated by the two controllers. The cost function is $k^2 \mathbb{E}\left[u_w^2 \right] + \mathbb{E}\left[x_2^2 \right]$ for some constant k. The initial state x_0 and the noise z at the input of the blurry controller are assumed to be Gaussian distributed and independent, with variances σ_0^2 and 1 respectively. The problem is a "linear-quadratic-Gaussian" (LQG) problem, i.e., the state evolution is linear, the costs are quadratic, and the primitive random variables are Gaussian.

Why is the problem called a "counterexample"? The traditional "certainty-equivalence" principle (Bertsekas 1995) shows that for all centralized LQG problems, linear control laws are optimal. Witsenhausen (1968) provided a nonlinear strategy for the Witsenhausen problem which outperforms all linear strategies. Thus, the counterexample showed that the certainty-equivalence doctrine does not extend to decentralized control.

What is this strategy of Witsenhausen that outperforms all linear strategies? It is, in fact, a quantization-based strategy, as suggested in our inverted-pendulum story above. Further, it was shown by Mitter and Sahai (1999) that multipoint quantization strategies can outperform linear strategies by an arbitrarily large factor! This observation, combined with the simplicity of the counterexample, makes the problem very

important in decentralized control. This simple two-time-step two-controller LQG problem needs to be understood to have any hope of understanding larger and more complex problems.

While the optimal costs for the problem are still unknown (even though it is known that an optimal strategy exists (Witsenhausen 1968; Wu and Verdú 2011)), there exists a wealth of understanding of the counterexample that has helped address more complicated problems. A body of work, starting with that of Baglietto et al. (1997), numerically obtained solutions that could be close to optimal (although there is no mathematical proof thereof). All these solutions have a consistent form (illustrated in Fig. 4), with slight improvements in the optimal cost. Because the discrete version of the problem, appropriately relaxed, is known to be NP-complete (Papadimitriou and Tsitsiklis 1986), this approach cannot be used to understand the entire parameter space and hence has focused on one point: $k^2 = 0.5, \sigma_0^2 = 5$. Nevertheless, the approach has proven to be insightful: a recent information-theoretic body of work shows that the strategies of Fig. 4 can be thought of as information-theoretic strategies of "dirty-paper coding" Costa (1983) that is related to the idea of

embedding information in the state. The question here is: how do we embed the information about the state *in the state itself*?

An information-theoretic view of the counterexample: This information-theoretic approach that culminated in Grover et al. (2013) also obtained the first approximately optimal solutions to the Witsenhausen counterexample as well as its vector extensions. The result is established by analyzing information flows in the counterexample that work toward minimizing the knowledge gradient, effectively an information pattern in which C_w can predict the observation of C_b more precisely. The analysis provides *an information-theoretic lower bound on cost that holds irrespective of what strategy is used*. For the original problem, this characterizes the optimal costs (with associated strategies) within a factor of 8 for all problem parameters (i.e., k and σ_0^2). For any finite-length extension, uniform finite-ratio approximations also exist (Grover et al. 2013). The asymptotically infinite-length extension has been solved *exactly* (Choudhuri and Mitra 2012).

The problem has also driven delineation of decentralized LQG control problems with optimal linear solutions and those with nonlinear optimal solutions. This led to the development and understanding of many variations of the counterexample (Bansal and Başar 1987; Başar 2008; Ho et al. 1978; Rotkowitz 2006) and understanding that can extend to larger decentralized control problems. More recent work shows that the promise of the Witsenhausen counterexample was not a misplaced one: the information-theoretic approach that provides approximately optimal solutions to the counterexample (Grover et al. 2013) yields solutions to other more complex (e.g., multi-controller, more time-steps) problems as well (Grover 2010; Park and Sahai 2012).

by the Witsenhausen counterexample. However, nonclassical information pattern for some simple problems – starting with the counterexample – has recently been explored via an information-theoretic lens, yielding the first optimal or approximately optimal solutions to these problems. This approach is promising for larger decentralized control problems as well. It is now important to explore what is the simplest decentralized control problem that cannot be solved (exactly or approximately) using ideas developed for the counterexample. In this manner, the Witsenhausen counterexample can provide a platform to unify the more modern (i.e., external-channel centric approaches, see ▶ Quantized Control and Data Rate Constraints; ▶ Data Rate of Nonlinear Control Systems and Feedback Entropy; ▶ Networked Control Systems: Architecture and Stability Issues; ▶ Networked Control Systems: Estimation and Control Over Lossy Networks; ▶ Information and Communication Complexity of Networked Control Systems; in the encyclopedia) with the more classical decentralized LQG problems, leading to enriching and useful formulations.

Information-Based Multi-Agent Systems

Wing-Shing Wong[1] and John Baillieul[2]
[1]Department of Information Engineering, The Chinese University of Hong Kong, Hong Kong, China
[2]Mechanical Engineering, Electrical and Computer Engineering, Boston University, Boston, MA, USA

Abstract

Multi-agent systems are encountered in nature (animal groups), in various domains of technology (multi-robot networks, mixed robot-human teams) and in various human activities (such as dance and team athletics). Information exchange among agents ranges from being incidentally important to crucial in such systems. Several systems in which information exchange among the agents is either a primary goal or a primary enabler are discussed briefly. Specific topics include power management in wireless communication networks, data-rate constraints, the complexity of distributed control, robotics networks and formation control, action-mediated communication, and multi-objective distributed systems.

Keywords

Distributed control; Information constraints; Multi-agent systems

Introduction

The role of information patterns in the decentralized control of multi-agent systems has been studied in different theoretical contexts for more than five decades. The paper Ho (1972) provides references to early work in this area. While research on distributed decision making has continued, a large body of recent research on robotic networks has brought new dimensions of geometric aspects of information patterns to the

forefront (Bullo et al. 2009). At the same time, machine intelligence, machine learning, machine autonomy, and theories of operation of mixed teams of humans and robots have considerably extended the intellectual frontiers of information-based multi-agent systems (Baillieul et al. 2012). A further important development has been the study of action-mediated communication and the recently articulated theory of *control communication complexity* (Wong and Baillieul 2012). These developments may shed light on nonverbal forms of communication among biological organisms (including humans) and on the intrinsic energy requirements of information processing.

In conventional decentralized control, the control objective is usually well-defined and known to all agents. Multi-agent information-based control encompasses a broader scenario, where the objective can be agent dependent and is not necessarily explicitly announced to all. For illustration, consider the power control problem in wireless communication – one of the earliest engineering systems that can be regarded as multi-agent information based. It is common that multiple transmitter-receiver communication pairs share the same radio frequency band and the transmission signals interfere with each other. The power control problem searches for feedback control for each transmitter to set its power level. The goal is for each transmitter to achieve targeted signal-to-interference ratio (SIR) level by using information of the observed levels at the intended receiver only.

A popular version of the power control problem (Foschini and Miljanic 1993) defines each individual objective target level by means of a requirement threshold, known only to the intended transmitter. As SIR measurements naturally reside on a receiver, the observed SIR needs to be communicated back to the transmitter. For obvious reasons, the bandwidth for such communication is limited. The resulting model fits the bill of multi-agent information-based control. In Sung and Wong (1999), a tristate power control strategy is proposed so that the power control outputs are either increased or decreased by a fixed dB or no change at all. Convergence of the feedback

algorithm was shown using a Lyapunov-like function.

This entry surveys key topics related to multi-agent information-based control systems, including control complexity, control with data-rate constraints, robotic networks and formation control, action-mediated communication, and multi-objective distributed systems.

Control Complexity

In information-based distributed control systems, how to efficiently share computational and communication resources is a fundamental issue. One of the earliest investigations on how to schedule communication resources to support a network of sensors and actuators is discussed in Brockett (1995). The concept of *communication sequencing* was introduced to describe how the communication channel is utilized to convey feedback control information in a network consisting of interacting subsystems. In Brockett (1997), the concept of *control attention* was introduced to provide a measure of the complexity of a control law against its performance. As attention is a shared, limited resource, the goal is to find minimum attention control. Another approach to gauge control complexity in a distributed system is by means of the minimum amount of communicated data required to accomplish a given control task.

Control with Data-Rate Constraints

A fundamental challenge in any control implementation in which system components communicate with each other over communication links is ensuring that the channel capacity is large enough to deal with the fastest time constants among the system components. In a single agent system, the so-called Data-Rate Theorem has been formulated in various ways to understand the constraints imposed between the sensor and the controller and between the controller and the actuator. Extensions to this fundamental result have been focused on addressing similar

problems in the network control system context. Information on such extensions in the distributed control setting can be found in Nair and Evans (2004) and Yüksel and Basar (2007).

Robotic Networks and Formation Control

The defining characteristic of robotic networks within the larger class of multi-agent systems is the centrality of spatial relationships among network nodes. Graph theory has been shown to provide a generally convenient mathematical language in which to describe spatial concepts and it is the key to understanding spatial rigidity related to the control of formations of autonomous vehicles (Anderson et al. 2008), or in flocking systems (Leonard et al. 2012), or in consensus problems (Su and Huang 2012), or in rendezvous problems (Cortés et al. 2006). For these distributed control research topics, readers can consult other sections in this Encyclopedia for a comprehensive reference list.

Much of the recent work on formation control has included information limitation considerations. For consensus problems, for example, Olfati-Saber and Murray (2004) introduced a sensing cost constraint, and in Ren and Beard (2005) information exchange constraints are considered, and in Yu and Wang (2010) communication delays are explicitly modeled.

Action-Mediated Communication

Biological organisms communicate through motion. Examples of this include prides of lions or packs of wolves whose pursuit of prey is a cooperative effort and competitive team athletics in the case of humans. Recent research has been aimed at developing a theoretical foundation of action-mediated communication. Communication protocols for motion-based signaling between mobile robots have been developed (Raghunathan and Baillieul 2009) and preliminary steps towards a theory of artistic expression through controlled

movements in dance have been reported in Baillieul and Özcimder (2012). Motion-based communication of this type involves specially tailored motion description languages in which sequences of motion primitives are assembled with the objective of conveying artistic intent, while minimizing the use of limited energy resources in carrying out the movement. These motion primitives constitute the *alphabet* that enables communication, and physical constraints on the motions define the grammatical rules that govern the ways in which motion sequences may be constructed.

Research on action-mediated communication helps illustrate the close connection between control and information theory. Further discussion of the deep connection between the two can be found, for example, in Park and Sahai (2011), which argues for the equivalence between the stabilization of a distributed linear system and the capacity characterization in linear network coding.

Multi-objective Distributive Systems

In a multi-agent system, agents may aim to carry out individual objectives. These objectives can either be cooperatively aligned (such as in a cooperative control setting) or may contend antagonistically (such as in a zero-sum game setting). In either case, a common assumption is that the objective functions are a priori known to all agents. However, in many practical applications, agents do not know the objectives of other agents, at least not precisely. For example, in the power control problem alluded to earlier, the signal-to-interference requirement of a user may be unknown to other users. Yet this does not prevent the possibility of deriving convergence algorithms to allow the joint goals to be achieved.

The issue of unknown objectives in a multi-agent system is formally analyzed in Wong (2009) via the introduction of choice-based actions. In an open access network, objectives of an individual agent may be known only partially, via the form of a random distribution in some cases. In order to achieve a joint control objective in general, some communication via the system

is required if there is no side communications channel. A basic issue is how to measure the minimum amount of information exchange that is required to perform a specific control task. Motivated by the idea of communication complexity in computer science, the idea of control communication complexity was introduced in Wong (2009), which can provide such a measure. In Wong and Baillieul (2009), the idea was extended to a rich class of nonlinear systems that arise as models of physical processes ranging from rigid body mechancs to quantum spin systems.

In some special cases, control objectives can be achieved without any communication among the agents. For systems with bilinear input–output mapping, including the Brockett Integrator, it is possible to derive conditions that guarantee this property (Wong and Baillieul 2012). Moreover, for quadratic type of control cost, it is possible to compute the optimal control cost. Similar results can be extended to linear systems as discussed in Liu et al. (2013). This circle of ideas is connected to the so-called *standard parts* problem as investigated in Baillieul and Wong (2009). Another connection is to *correlated equilibrium* problems that have been recently studied by game theorists Shoham and Leyton-Brown (2009).

Input-to-State Stability

Eduardo D. Sontag
Rutgers University, New Brunswick, NJ, USA

Synonyms

ISS

Abstract

The notion of input to state stability (ISS)
qualitatively describes stability of the mapping
from initial states and inputs to internal states
(and more generally outputs). This entry focuses
on the definition of ISS and a discussion of
equivalent characterizations.

Keywords

Asymptotic stability; Dissipation; Lyapunov
functions

Introduction

We consider here systems with inputs in the usual
sense of control theory:

$$\dot{x}(t) = f(x(t), u(t))$$

(the arguments "t" are often omitted). There
are n state variables and m input channels.
States $x(t)$ take values in Euclidean space
$\mathbb{R}^n$, and the inputs (also called "controls"
or "disturbances" depending on the context)
are measurable in locally essentially bounded
maps $u(\cdot) : [0, \infty) \to \mathbb{R}^m$. The map $f :
\mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$ is assumed to be locally
Lipschitz with $f(0, 0) = 0$. The solution, defined
on some maximal interval $[0, t_{\max}(x^0, u))$, for
each initial state x^0 and input u, is denoted as
$x(t, x^0, u)$ and, in particular, for systems with
no inputs $\dot{x}(t) = f(x(t))$, just as $x(t, x^0)$. The
zero system associated to $\dot{x} = f(x, u)$ is by
definition the system with no inputs $\dot{x} = f(x, 0)$.
Euclidean norm is written as $|x|$. For a function
of time, typically an input or a state trajectory,
$\|u\|$, or $\|u\|_\infty$ for emphasis, is the (essential)
supremum or "sup" norm (possibly $+\infty$, if u is
not bounded). The norm of the restriction of a
signal to an interval I is denoted by $\|u_I\|_\infty$ (or
just $\|u_I\|$).

Input-to-State Stability

It is convenient to introduce "comparison func-
tions" to quantify stability. A *class $\mathcal{K}_\infty$ function*
is a function $\alpha : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ which is con-
tinuous, strictly increasing, and unbounded and
satisfies $\alpha(0) = 0$, and a *class $\mathcal{KL}$ function* is
a function $\beta : \mathbb{R}_{\geq 0} \times \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ such that
$\beta(\cdot, t) \in \mathcal{K}_\infty$ for each t and $\beta(r, t)$ decreases to
zero as $t \to \infty$, for each fixed r.

For a system with no inputs $\dot{x} = f(x)$, there is a well-known notion of global asymptotic stability (for short from now on, *GAS*, or "*0-GAS*" when referring to the zero system $\dot{x} = f(x, 0)$ associated to a given system with inputs $\dot{x} = f(x, u)$) due to Lyapunov and usually defined in "ϵ-δ" terms. It is an easy exercise to show that this standard definition is in fact equivalent to the following statement:

$$(\exists \beta \in \mathcal{KL}) |x(t, x^0)| \le \beta\left(|x^0|, t\right) \forall x^0, \ \forall t \ge 0.$$

The notion of input to state stability (ISS) was introduced in Sontag (1989), and it provides theoretical concepts used to describe stability features of a mapping $(u(\cdot), x(0)) \alpha x(\cdot)$ that sends initial states and input functions into states (or, more generally, outputs). Prominent among these features are that inputs that are bounded, "eventually small," "integrally small," or convergent should lead to outputs with the respective property. In addition, ISS and related notions quantify in what manner initial states affect transient behavior. The formal definition is as follows.

A system is said to be *input to state stable (ISS)* if there exist some $\beta \in \mathcal{KL}$ and $\gamma \in \mathcal{K}_\infty$ such that

$$|x(t)| \le \beta\left(|x^0|, t\right) + \gamma\left(\|u\|_\infty\right) \quad \text{(ISS)}$$

holds for all solutions (meaning that the estimate is valid for all inputs $u(\cdot)$, all initial conditions x^0, and all $t \ge 0$). Note that the supremum $\sup_{s \in [0,t]} \gamma(|u(s)|)$ over the interval $[0, t]$ is the same as $\gamma(\|u_{[0,t]}\|_\infty) = \gamma(\sup_{s \in [0,t]}(|u(s)|))$, because the function γ is increasing, so one may replace this term by $\gamma(\|u\|_\infty)$, where $\|u\|_\infty = \sup_{s \in [0,\infty)} \gamma(|u(s)|)$ is the sup norm of the input, because the solution $x(t)$ depends only on values $u(s), s \le t$ (so, one could equally well consider the input that has values $\equiv 0$ for all $s > t$).

Since, in general, $\max\{a, b\} \le a + b \le \max\{2a, 2b\}$, one can restate the ISS condition in a slightly different manner, namely, asking for the existence of some $\beta \in \mathcal{KL}$ and $\gamma \in \mathcal{K}_\infty$ (in general, different from the ones in the ISS definition) such that
Input-to-State Stability, Fig. 1 ISS combines overshoot and asymptotic behavior

$$|x(t)| \le \max\left\{\beta(|x^0|, t), \ \gamma\left(\|u\|_\infty\right)\right\}$$

holds for all solutions. Such redefinitions, using "max" instead of sum, are also possible for each of the other concepts to be introduced later.

Intuitively, the definition of ISS requires that, for t large, the size of the state must be bounded by some function of the sup norm – that is to say, the amplitude – of inputs (because $\beta(|x^0|, t) \to 0$ as $t \to \infty$). On the other hand, the $\beta(|x^0|, 0)$ term may dominate for small t, and this serves to quantify the magnitude of the transient (overshoot) behavior as a function of the size of the initial state x^0 (Fig. 1). The *ISS superposition theorem*, discussed later, shows that ISS is, in a precise mathematical sense, the conjunction of two properties, one of them dealing with asymptotic bounds on $|x^0|$ as a function of the magnitude of the input and the other one providing a transient term obtained when one ignores inputs.

For internally stable linear systems $\dot{x} = Ax + Bu$, the variation of parameters formula gives immediately the following inequality:

$$|x(t)| \le \beta(t) |x^0| + \gamma \|u\|_\infty,$$

where

$$\beta(t) = \left\|e^{tA}\right\| \to 0 \quad \text{and}$$

$$\gamma = \|B\| \int_0^\infty \left\|e^{sA}\right\| ds < \infty.$$

This is a particular case of the ISS estimate, $|x(t)| \leq \beta(|x^0|, t) + \gamma(\|u\|_\infty)$, with linear comparison functions.

Feedback Redesign

The notion of ISS arose originally as a way to precisely formulate, and then answer, the following question. Suppose that, as in many problems in control theory, a system $\dot{x} = f(x, u)$ has been stabilized by means of a feedback law $u = k(x)$ (Fig. 2), that is to say, k was chosen such that the origin of the closed-loop system $\dot{x} = f(x, k(x))$ is globally asymptotically stable. (See, e.g., Sontag 1999 for a discussion of mathematical aspects of state feedback stabilization.) Typically, the design of k was performed by ignoring the effect of possible *input disturbances* $d(\cdot)$ (also called actuator disturbances). These "disturbances" might represent true noise or perhaps errors in the calculation of the value $k(x)$ by a physical controller or modeling uncertainty in the controller or the system itself. What is the effect of considering disturbances? In order to analyze the problem, d is incorporated into the model, and one studies the new system $\dot{x} = f(x, k(x) + d)$, where d is seen as an input (Fig. 3). One may then ask what is the effect of d on the behavior of the system. Disturbances d may well destabilize the system, and the problem may arise even when using a routine technique for control design, feedback linearization. To appreciate this issue, take the following very simple example. Given is the system

$$\dot{x} = f(x, u) = x + (x^2 + 1)u.$$

In order to stabilize it, substitute $u = \frac{\tilde{u}}{x^2+1}$ (a preliminary feedback transformation), rendering the system linear with respect to the new input $\tilde{u}$: $\dot{x} = x + \tilde{u}$, and then use $\tilde{u} = -2x$ in order to obtain the closed-loop system $\dot{x} = -x$. In other words, in terms of the original input u, the feedback law is

$$k(x) = \frac{-2x}{x^2 + 1}$$
Input-to-State Stability, Fig. 2 Feedback stabilization, closed-loop system $\dot{x} = f(x, k(x))$
Input-to-State Stability, Fig. 3 Actuator disturbances, closed-loop system $\dot{x} = f(x, k(x) + d)$

so that $f(x, k(x)) = -x$. This is a GAS system. The effect of the disturbance input d is analyzed as follows. The system $\dot{x} = f(x, k(x) + d)$ is

$$\dot{x} = -x + (x^2 + 1)d.$$

This system has solutions which diverge to infinity even for inputs d that converge to zero; moreover, the constant input $d \equiv 1$ results in solutions that explode in finite time. Thus $k(x) = \frac{-2x}{x^2+1}$ was not a good feedback law, in the sense that its performance degraded drastically once actuator disturbances were taken into account.

The key observation for what follows is that if one adds a correction term "$-x$" to the above formula for $k(x)$, so that now,

$$\tilde{k}(x) = \frac{-2x}{x^2 + 1} - x,$$

then the system $\dot{x} = f(x, \tilde{k}(x) + d)$ with disturbance d as input becomes instead

$$\dot{x} = -2x - x^3 + (x^2 + 1)d$$

and this system is much better behaved: it is still GAS when there are no disturbances (it reduces

to $\dot{x} = -2x - x^3$), but, in addition, it is ISS (easy to verify directly, or appealing to some of the characterizations mentioned later). Intuitively, for large x, the term $-x^3$ serves to dominate the term $(x^2 + 1)d$, for all bounded disturbances $d(\cdot)$, and this prevents the state from getting too large.

This example is an instance of a general result, which says that, whenever there is some feedback law that stabilizes a system, there is also a (possibly different) feedback so that the system with external input d is ISS.

Theorem 1 (Sontag 1989). *Consider a system affine in controls*

$$\dot{x} = f(x, u) = g_0(x) + \sum_{i=1}^{m} u_i g_i(x) \ (g_0(0) = 0)$$

and suppose that there is some differentiable feedback law $u = k(x)$ so that

$$\dot{x} = f(x, k(x))$$

has $x = 0$ as a GAS equilibrium. Then, there is a feedback law $u = \widetilde{k}(x)$ such that

$$\dot{x} = f(x, \widetilde{k}(x) + d)$$

is ISS with input $d(\cdot)$.

The reader is referred to the book Krstić et al. (1995), and the references given later, for many further developments on the subjects of recursive feedback design, the "backstepping" approach, and other far-reaching extensions.

Equivalences for ISS

This section reviews results that show that ISS is equivalent to several other notions, including asymptotic gain, existence of robustness margins, dissipativity, and an energy-like stability estimate.

Nonlinear Superposition Principle

Clearly, if a system is ISS, then the system with no inputs $\dot{x} = f(x, 0)$ is GAS: the term $\|u\|_\infty$

vanishes, leaving precisely the GAS property. In particular, then, the system $\dot{x} = f(x, u)$ is *0-stable*, meaning that the origin of the system without inputs $\dot{x} = f(x, 0)$ is stable in the sense of Lyapunov: for each $\epsilon > 0$, there is some $\delta > 0$ such that $|x^0| < \delta$ implies $|x(t, x^0)| < \epsilon$. (In comparison-function language, one can restate 0-stability as follows: there is some $\gamma \in \mathcal{K}$ such that $|x(t, x^0)| \leq \gamma(|x^0|)$ holds for all small x^0.)

On the other hand, since $\beta(|x^0|, t) \to 0$ as $t \to \infty$, for t large one has that the first term in the ISS estimate $|x(t)| \leq \max\{\beta(|x^0|, t), \gamma(\|u\|_\infty)\}$ vanishes. Thus an ISS system satisfies the following *asymptotic gain property ("AG"):* there is some $\gamma \in \mathcal{K}_\infty$ so that:

$$\varlimsup_{t \to +\infty} |x(t, x^0, u)| \leq \gamma(\|u\|_\infty) \quad \forall x^0, u(\cdot) \tag{AG}$$

(see Fig. 4). In words, for all large enough t, the trajectory exists, and it gets arbitrarily close to a sphere whose radius is proportional, in a possibly nonlinear way quantified by the function γ, to the amplitude of the input. In the language of robust control, the estimate (AG) would be called an "ultimate boundedness" condition; it is a generalization of attractivity (all trajectories converge to zero, for a system $\dot{x} = f(x)$ with no inputs) to the case of systems with inputs; the "lim sup" is required since the limit of $x(t)$ as $t \to \infty$ may well not exist. From now on (and analogously when defining other properties), we
Input-to-State Stability, Fig. 4 Asymptotic gain property

will just say "the system is AG" instead of the more cumbersome "satisfies the AG property."

Observe that, since only large values of t matter in the limsup, one can equally well consider merely tails of the input u when computing its sup norm. In other words, one may replace $\gamma(\|u\|_\infty)$ by $\gamma(\overline{\lim}_{t \to +\infty} |u(t)|)$, or (since γ is increasing) $\overline{\lim}_{t \to +\infty} \gamma(|u(t)|)$.

The surprising fact is that these two necessary conditions are also sufficient. This is summarized by the *ISS superposition theorem*:

Theorem 2 (Sontag and Wang 1996). *A system is ISS if and only if it is 0-stable and AG.*

A minor variation of the above superposition theorem is as follows. Let us consider the *limit property (LIM)*:

$$\inf_{t \geq 0} |x(t, x^0, u)| \leq \gamma(\|u\|_\infty) \quad \forall\, x^0, u(\cdot) \quad \text{(LIM)}$$

(for some $\gamma \in \mathcal{K}_\infty$).

Theorem 3 (Sontag and Wang 1996). *A system is ISS if and only if it is 0-stable and LIM.*

Robust Stability

In this entry, a system is said to be *robustly stable* if it admits a *margin of stability* ρ, that is, a smooth function $\rho \in \mathcal{K}_\infty$ so the system

$$\dot{x} = g(x, d) := f(x, d\rho(|x|))$$

is GAS uniformly in this sense: for some $\beta \in \mathcal{KL}$,

$$\left| x(t, x^0, d) \right| \leq \beta(|x^0|, t)$$

for all possible $d(\cdot) : [0, \infty) \to [-1, 1]^m$. An alternative way to interpret this concept (cf. Sontag and Wang 1995) is as uniform global asymptotic stability of the origin with respect to all possible time-varying feedback laws Δ bounded by ρ: $|\Delta(t, x)| \leq \rho(|x|)$. In other words, the system

$$\dot{x} = f(x, \Delta(t, x))$$

(Fig. 5) is stable uniformly over all such perturbations Δ. In contrast to the ISS definition, which deals with all possible "open-loop" inputs, the
Input-to-State Stability, Fig. 5 Margin of robustness

present notion of robust stability asks about all possible closed-loop interconnections. One may think of Δ as representing uncertainty in the dynamics of the original system, for example.

Theorem 4 (Sontag and Wang 1995). *A system is ISS if and only if it is robustly stable.*

Intuitively, the ISS estimate $|x(t)| \leq \max\{\beta(|x^0|, t), \gamma(\|u\|_\infty)\}$ says that the β term dominates as long as $|u(t)| \ll |x(t)|$ for all t, but $|u(t)| \ll |x(t)|$ amounts to $u(t) = d(t).\rho(|x(t)|)$ with an appropriate function ρ. This is an instance of a "small gain" argument, see below. One analog for linear systems is as follows: if A is a Hurwitz matrix, then $A + Q$ is also Hurwitz, for all small enough perturbations Q; note that when Q is a nonsingular matrix, $|Qx|$ is a $\mathcal{K}_\infty$ function of $|x|$.

Dissipation

Another characterization of ISS is as a dissipation notion stated in terms of a Lyapunov-like function. A continuous function $V : \mathbb{R}^n \to \mathbb{R}$ is said to be a *storage function* if it is positive definite, that is, $V(0) = 0$ and $V(x) > 0$ for $x \neq 0$, and proper, that is, $V(x) \to \infty$ as $|x| \to \infty$. This last property is equivalent to the requirement that the sets $V^{-1}([0, A])$ should be compact subsets of $\mathbb{R}^n$, for each $A > 0$, and in the engineering literature, it is usual to call such functions *radially unbounded*. It is an easy exercise to show that $V : \mathbb{R}^n \to \mathbb{R}$ is a storage function if and only if there exist $\underline{\alpha}, \overline{\alpha} \in \mathcal{K}_\infty$ such that

$$\underline{\alpha}(|x|) \leq V(x) \leq \overline{\alpha}(|x|) \quad \forall\, x \in \mathbb{R}^n$$

(the lower bound amounts to properness and $V(x) > 0$ for $x \neq 0$, while the upper bound guarantees $V(0) = 0$). For convenience, $\dot{V} : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}$ is the function:

$$\dot{V}(x, u) := \nabla V(x) . f(x, u)$$

which provides, when evaluated at $(x(t), u(t))$, the derivative $dV(x(t))/dt$ along solutions of $\dot{x} = f(x, u)$.

An *ISS-Lyapunov function* for $\dot{x} = f(x, u)$ is by definition a smooth storage function V for which there exist functions $\gamma, \alpha \in \mathcal{K}_\infty$ so that

$$\dot{V}(x, u) \ \leq \ -\alpha(|x|) + \gamma(|u|) \quad \forall\, x, u\,.$$
(L-ISS)

Integrating, an equivalent statement is that, along all trajectories of the system, there holds the following dissipation inequality:

$$V(x(t_2)) - V(x(t_1)) \ \leq \ \int_{t_1}^{t_2} w(u(s), x(s))\, ds$$

where, using the terminology of Willems (1976), the "supply" function is $w(u, x) = \gamma(|u|) - \alpha(|x|)$. For systems with no inputs, an ISS-Lyapunov function is precisely the same object as a Lyapunov function in the usual sense.

Theorem 5 (Sontag and Wang 1995). *A system is ISS if and only if it admits a smooth ISS-Lyapunov function.*

Since $-\alpha(|x|) \leq -\alpha(\overline{\alpha}^{-1}(V(x)))$, the ISS-Lyapunov condition can be restated as

$$\dot{V}(x, u) \ \leq \ -\tilde{\alpha}(V(x)) + \gamma(|u|) \quad \forall\, x, u$$

for some $\tilde{\alpha} \in \mathcal{K}_\infty$. In fact, one may strengthen this a bit (Praly and Wang 1996): for any ISS system, there is a always a smooth ISS-Lyapunov function satisfying the "exponential" estimate $\dot{V}(x, u) \leq -V(x) + \gamma(|u|)$.

The sufficiency of the ISS-Lyapunov condition is easy to show and was already in the original paper Sontag (1989). A sketch of proof is as follows, assuming for simplicity a dissipation estimate in the form $\dot{V}(x, u) \leq -\alpha(V(x)) + \gamma(|u|)$. Given any x and u, either $\alpha(V(x)) \leq 2\gamma(|u|)$

or $\dot{V} \leq -\alpha(V)/2$. From here, one deduces by a comparison theorem that, along all solutions,

$$V(x(t)) \leq \max\left\{ \beta(V(x^0), t), \alpha^{-1}(2\gamma(\|u\|_\infty)) \right\},$$

where the $\mathcal{KL}$ function $\beta(s, t)$ is the solution $y(t)$ of the initial value problem

$$\dot{y} = -\frac{1}{2}\alpha(y) + \gamma(u), \quad y(0) = s.$$

Finally, an ISS estimate is obtained from $V(x^0) \leq \overline{\alpha}(x^0)$.

The proof of the converse part of the theorem is based upon first showing that ISS implies robust stability in the sense already discussed and then obtaining a converse Lyapunov theorem for robust stability for the system $\dot{x} = f(x, d\rho(|x|)) = g(x, d)$, which is asymptotically stable uniformly on all Lebesgue-measurable functions $d(\cdot) : \mathbb{R}_{\geq 0} \to B(0, 1)$. This last theorem was given in Lin et al. (1996) and is basically a theorem on Lyapunov functions for differential inclusions. The classical result of Massera (1956) for differential equations (with no inputs) becomes a special case.

Using "Energy" Estimates Instead of Amplitudes

In linear control theory, H_∞ theory studies $L^2 \to L^2$ induced norms, which under coordinate changes leads to the following type of estimate:

$$\int_0^t \alpha\,(|x(s)|))\, ds \ \leq \ \alpha_0(|x^0|) + \int_0^t \gamma(|u(s)|)\, ds$$

along all solutions and for some $\alpha, \alpha_0, \gamma \in \mathcal{K}_\infty$. Just for the statement of the next result, a system is said to *satisfy an integral-integral estimate* if for every initial state x^0 and input u, the solution $x(t, x^0, u)$ is defined for all $t > 0$ and an estimate as above holds. (In contrast to ISS, this definition explicitly demands that $t_{\max} = \infty$.)

Theorem 6 (Sontag 1998). *A system is ISS if and only if it satisfies an integral-integral estimate.*

This theorem is quite easy to prove, in view of previous results. A sketch of proof is as follows. If the system is ISS, then there is an ISS-Lyapunov function satisfying $\dot{V}(x, u) \le -V(x) + \gamma(|u|)$, so, integrating along any solution:

$$\int_0^t V(x(s))\,ds \le \int_0^t V(x(s))\,ds + V(x(t))$$
$$\le V(x(0)) + \int_0^t \gamma(|u(s)|)\,ds$$

and thus an integral-integral estimate holds. Conversely, if such an estimate holds, one can prove that $\dot{x} = f(x, 0)$ is stable and that an asymptotic gain exists.

Integral Input to State Stability

A concept of nonlinear stability that is truly distinct from ISS arises when considering a mixed notion which combines the "energy" of the input with the amplitude of the state. A system is said to be *integral-input to state stable (iISS)* provided that there exist $\alpha, \gamma \in \mathcal{K}_\infty$ and $\beta \in \mathcal{KL}$ such that the estimate

$$\alpha\left(|x(t)|\right) \le \beta(|x^0|, t) + \int_0^t \gamma(|u(s)|)\,ds \tag{iISS}$$

holds along all solutions. Just as with ISS, one could state this property merely for all times $t \in t_{\max}(x^0, u)$. Since the right-hand side is bounded on each interval $[0, t]$ (because, recall, inputs are by definition assumed to be bounded on each finite interval), it is automatically true that $t_{\max}(x^0, u) = +\infty$ if such an estimate holds along maximal solutions. So forward-completeness (solution exists for all $t > 0$) can be assumed with no loss of generality.

One might also consider the following type of "weak integral to integral" mixed estimate:

$$\int_0^t \underline{\alpha}(|x(s)|)\,ds \le \kappa(|x^0|)$$

$$+ \alpha\left(\int_0^t \gamma(|u(s)|)\,ds\right)$$

for appropriate $\mathcal{K}_\infty$ functions (note the additional "α").

Theorem 7 (Angeli et al. 2000b). *A system satisfies a weak integral to integral estimate if and only if it is iISS.*

Another interesting variant is found when considering mixed *integral/supremum* estimates:

$$\underline{\alpha}(|x(t)| \le \beta(|x^0|, t) + \int_0^t \gamma_1(|u(s)|)\,ds$$
$$+ \gamma_2(\|u\|_\infty)$$

for suitable $\beta \in \mathcal{KL}$ and $\underline{\alpha}, \gamma_i \in \mathcal{K}_\infty$. One then has

Theorem 8 (Angeli et al. 2000b). *A system satisfies a mixed estimate if and only if it is iISS.*

Dissipation Characterization of iISS
A smooth storage function V is an *iISS-Lyapunov function* for the system $\dot{x} = f(x, u)$ if there are a $\gamma \in \mathcal{K}_\infty$ and an $\alpha : [0, +\infty) \to [0, +\infty)$ which is merely *positive definite* (i.e., $\alpha(0) = 0$ and $\alpha(r) > 0$ for $r > 0$) such that the inequality

$$\dot{V}(x, u) \le -\alpha(|x|) + \gamma(|u|) \tag{L-iISS}$$

holds for all $(x, u) \in \mathbb{R}^n \times \mathbb{R}^m$. To compare, recall that an ISS-Lyapunov function is required to satisfy an estimate of the same form but where α is required to be of class $\mathcal{K}_\infty$; since every $\mathcal{K}_\infty$ function is positive definite, an ISS-Lyapunov function is also an iISS-Lyapunov function.

Theorem 9 (Angeli et al. 2000a). *A system is iISS if and only if it admits a smooth iISS-Lyapunov function.*

Since an ISS-Lyapunov function is also an iISS one, ISS implies iISS. However, iISS is a strictly weaker property than ISS, because α may be bounded in the iISS-Lyapunov estimate, which means that V may increase, and the state become unbounded, even under bounded inputs, so long

as $\gamma(|u(t)|)$ is larger than the range of α. This is also clear from the iISS definition, since a constant input with $|u(t)| = r$ results in a term in the right-hand side that grows like rt.

An interesting general class of examples is given by *bilinear* systems

$$\dot{x} = \left(A + \sum_{i=1}^{m} u_i A_i \right) x + Bu$$

for which the matrix A is Hurwitz. Such systems are always iISS (see Sontag 1998), but they are not in general ISS. For instance, in the case when $B = 0$, boundedness of trajectories for all constant inputs already implies that $A + \sum_{i=1}^{m} u_i A_i$ must have all eigenvalues with nonpositive real part, for all $u \in \mathbb{R}^m$, which is a condition involving the matrices A_i (e.g., $\dot{x} = -x + ux$ is iISS but it is not ISS).

The notion of iISS is useful in situations where an appropriate notion of detectability can be verified using LaSalle-type arguments. There follow two examples of theorems along these lines.

Theorem 10 (Angeli et al. 2000a). *A system is iISS if and only if it is 0-GAS and there is a smooth storage function V such that, for some $\sigma \in \mathcal{K}_\infty$:*
$$\dot{V}(x, u) \leq \sigma(|u|)$$
for all (x, u).

The sufficiency part of this result follows from the observation that the 0-GAS property by itself already implies the existence of a smooth and positive definite, but not necessarily proper, function V_0 such that $\dot{V}_0 \leq \gamma_0(|u|) - \alpha_0(|x|)$ for all (x, u), for some $\gamma_0 \in \mathcal{K}_\infty$ and positive definite α_0 (if V_0 were proper, then it would be an iISS-Lyapunov function). Now, one uses $V_0 + V$ as an iISS-Lyapunov function (V provides properness).

Theorem 11 (Angeli et al. 2000a). *A system is iISS if and only if there exists an output function $y = h(x)$ (continuous and with $h(0) = 0$) which provides zero detectability ($u \equiv 0$ and $y \equiv 0 \Rightarrow x(t) \rightarrow 0$) and dissipativity in the*

following sense: there exists a storage function V and $\sigma \in \mathcal{K}_\infty$, α positive definite, so that

$$\dot{V}(x, u) \leq \sigma(|u|) - \alpha(h(x))$$

holds for all (x, u).

Angeli et al. (2000b) contains several additional characterizations of iISS.

Superposition Principles for iISS

There are also asymptotic gain characterizations for iISS. A system is *bounded energy weakly converging state (BEWCS)* if there exists some $\sigma \in \mathcal{K}_\infty$ so that the following implication holds:

$$\int_0^{+\infty} \sigma(|u(s)|) \, ds < +\infty \quad \Rightarrow$$
$$\liminf_{t \to +\infty} |x(t, x^0, u)| = 0 \quad \text{BEWCS}$$

(more precisely: if the integral is finite, then $t_{\max}(x^0, u) = +\infty$ and the liminf is zero). It is *bounded energy frequently bounded state (BEFBS)* if there exists some $\sigma \in \mathcal{K}_\infty$ so that the following implication holds:

$$\int_0^{+\infty} \sigma(|u(s)|) \, ds < +\infty \quad \Rightarrow$$
$$\liminf_{t \to +\infty} |x(t, x^0, u)| < +\infty \quad \text{BEFBS}$$

(again, meaning that $t_{\max}(x^0, u) = +\infty$ and the lim inf is finite).

Theorem 12 (Angeli et al. 2004). *The following three properties are equivalent for any given system $\dot{x} = f(x, u)$:*
- *The system is iISS.*
- *The system is BEWCS and 0-stable.*
- *The system is BEFBS and 0-GAS.*

Summary and Future Directions

This entry focuses on stability notions relative to steady states, but a more general theory is also

possible that allows consideration of more arbitrary attractors, as well as robust and/or adaptive concepts. Much else has been omitted from this entry. Most importantly, one of the key results is the *ISS small-gain theorem* due to Jiang et al. (1994), which provides a powerful sufficient condition for the interconnection of ISS systems being itself ISS.

Other topics not treated include, among many others, all notions involving outputs; ISS properties of time-varying (and in particular periodic) systems; ISS for discrete-time systems; questions of sampling, relating ISS properties of continuous and discrete-time systems; ISS with respect to a closed subset K; stochastic ISS; applications to tracking, vehicle formations ("leader to followers" stability); and averaging of ISS systems. Sontag (2006) may also be consulted for further references, a detailed development of some of these ideas, and citations to the literature for others. In addition, the textbooks Isidori (1999), Krstić et al. (1995), Khalil (1996), Sepulchre et al. (1997), Krstić and Deng (1998), Freeman and Kokotović (1996), and Isidori et al. (2003) contain many extensions of the theory as well as applications.

Interactive Environments and Software Tools for CACSD

Vasile Sima
Advanced Research, National Institute for
Research & Development in Informatics,
Bucharest, Romania

Abstract

The main functional and support facilities offered by interactive environments and tools for computer-aided control system design (CACSD) and reference examples of such software systems are presented, from both a user and a developer perspective. The essential functions these environments should possess and requirements which should be satisfied are discussed. The importance of reliability and efficiency is highlighted, besides the desired friendliness and flexibility of the user interface. Widely used environments and software tools for CACSD, including MATLAB, Mathematica, Maple, and the SLICOT Library, serve as illustrative examples.

Keywords

Automatic control; Controller design; Numerical algorithms; Simulation; User interface

Introduction

The complexity of many processes or systems to be controlled, and the strong performance requirements to be fulfilled nowadays, makes it very difficult or even impossible to design suitable control laws and algorithms without resorting to computers and dedicated software tools. computer-aided control system design (CACSD) is the use of computer programs to support the creation, analysis, evaluation, or optimization of a control system design. CACSD is a specialization of computer-aided design (CAD) for control systems. CAD is used in many domains, to enhance designer's productivity and the design quality and to manage the design versions and documentation. CACSD is not a new paradigm, since the first such software systems have been developed about 50 years ago. See the historical overview in a companion paper.

The interactive environments and tools for CACSD have evolved significantly during the last decades, in parallel with the developments of numerical linear algebra, scientific computations, and computer hardware and software, including programming and networking capabilities. Starting from simple collections of specialized tools for solving well-defined system analysis and design problems, the CACSD became increasingly more sophisticated and powerful, allowing complicated tasks to be orchestrated for fully covering the stages of control engineering design, prototyping, and testing, including even the transfer to practical systems and applications. Modeling, system analysis and synthesis, and control system assessment are activities which are assisted by the nowadays advanced CACSD environments and software tools. The main aim is to help the designer to concentrate on the design problem itself, not on theoretical approaches, numerical algorithms, and computational details. Moreover, CACSD environments allow the developers and users to do conceptual thinking, but also programming and debugging at a higher level of abstraction, in comparison with standard programming languages, like Fortran, C/C++, or Java[TM].

There are both commercial or free and open-source CACSD environments and tools. State-of-the-art CACSD systems exist for several platforms (Windows, Linux/UNIX, and Mac OS X). Multiple high-speed CPUs, graphics cards, and large amounts of RAM are well suited to perform graphically and computationally intensive tasks. A common feature is the presence of a "friendly" graphical user interface, but often a dedicated command language is also available. The user interacts with the CACSD environment, e.g., by specifying the model or control structure, the design requirements, and the values of essential parameters or by selecting and combining

Interactive CACSD environment (e.g., MATLAB, Mathematica, Maple) (for modeling, simulation, analysis, synthesis, etc.)
Toolboxes or packages with executables or functions written in the environment language
(Graphical) User interface, Interactive language, Graphical functions, API
CACSD subroutine libraries (e.g., SLICOT)
Mathematical subroutine libraries (e.g., LAPACK, ARPACK, IMSL, NAG)
Computer-optimized mathematical libraries or their generators (e.g., BLAS, MKL, ATLAS)
Libraries of intrinsic functions (e.g., in Fortran or C/C++)

Interactive Environments and Software Tools for CACSD, Fig. 1 Hierarchy of the software components incorporated in an interactive CACSD environment

the tools to be used. The process can be repeated until a satisfactory behavior is obtained.

Usually, the underlying computational tools on which the interactive environments are based are hidden to the user. Moreover, software for extensive testing is not normally provided, but demonstrators running few examples are offered. Unfortunately, even mathematically simple problems of small dimension can conduct to wrong results when using unsuitable algorithms. Illustrative control-related examples are given, e.g., in Van Huffel et al. (2004). Since system analysis and design tasks usually involve sequential or iterative solution of large and complex subproblems, it follows that the quality of the intermediate results is of utmost importance. Consequently, the interactive environments for CACSD should be based on reliable, efficient, and thoroughly tested computational building blocks, which are called at the lower layers of calculations. These blocks constitute the computational engine of an interactive environment.

Figure 1 gives a typical hierarchy of the software components incorporated in an interactive CACSD environment.

Interactive Environments for CACSD

Main Functionality

A comprehensive set of functions of and requirements for interactive environments for control engineering are described in MacFarlane et al. (1989), but such a set has probably not yet been covered by any single environment. State-of-the-art interactive environments for CACSD include many attractive functional features:

- Define or find (via first principles or system identification) various system models (e.g., state-space models or transfer-function matrices) and convert between different representations
- Find reduced order (or simplified) models, which can more economically be used for simulation, control, prediction, etc.
- Analyze basic system properties, like stability, controllability, observability, stabilizability, detectability, minimality, properness, etc.
- Analyze interactively the behavior of a control system for various scenarios
- Provide alternative tools for different categories of users, from novice to expert, and from classical to "modern" or advanced analysis and synthesis techniques, in time domain or frequency domain
- Provide a wide range of tools, covering modeling, system identification, filtering, control system design, simulation, real-time behavior, hardware-in-the-loop simulation, and code generation for easy deployment and ensure their interoperability
- Allow the user to add extensions at various levels, new functions, interfaces, or even toolboxes or packages, which can be made available to a general community and allow customization

In addition to the functional and computational tools, essential components of an interactive environment are the user interface, the application program interface (API), and the support tools which enable to easily specify, document, and store a design solution, to visualize and interpret the results, to export them to other applications for further processing, to generate reports, etc.

A good paradigm for the data environment is object orientation.

It is a common feature of an interactive environment for CACSD to address the requirements of a large diversity of users, in various stages of familiarity with the environment. This feature is expressed, e.g., by the option to use either a graphical user interface or a command language to call and sequence various computational procedures. In addition, tools for easy building new computational or graphical procedures, or for managing the codes and results, are often included. The command language should operate both on low-level data constructs, such as a matrix, and on high-level ones (e.g., system objects), and it should allow operator overloading (e.g., taking $G_1 * G_2$ as the result of a series interconnection of the systems represented by the system objects G_1 and G_2).

An environment for CACSD should integrate advanced user interfaces and API, a collection of problem solvers based on reliable and efficient numerical and possibly symbolic algorithms, and tools for visualizing and interpreting the results. Widely used such environments are, for instance, MATLAB from The MathWorks, Inc., Mathematica from Wolfram Research, or Maple from Waterloo Maple Inc. (Maplesoft). Earlier developments of CACSD packages are surveyed in Frederick et al. (1991). There are also environments dedicated to modeling and simulation, which cover a broad range of technical and engineering computations, including those for mechanical, electrical, thermodynamic, hydraulic, pneumatic, or thermal systems. An example is Dymola, presented in a subsequent subsection.

Reference interactive environments and tools for CACSD are presented in the following (sub)sections.

Reference Interactive Environments

MATLAB (MATrix LABoratory) is an integrated, interactive environment for technical computing, visualization, and programming (MathWorks 2013). Based on a powerful high-level interpreter language and development tools, an easy-to-use, flexible, and customizable graphical user interface, complemented with attractive visualization capabilities, and open for extensions with new toolkits, MATLAB can be used for solving intricate scientific and engineering problems, as well as for the development and deployment of applications.

MATLAB$^{®}$ and Simulink$^{®}$ are registered trademarks of The MathWorks, Inc. MATLAB, Simulink, and several toolboxes, including System Identification Toolbox, Control System Toolbox, and Robust Control Toolbox, are suitable for solving various control engineering problems; other toolboxes, such as Signal Processing Toolbox, Optimization Toolbox, and Symbolic Math Toolbox, offer additional useful facilities. See http://www.mathworks.com/products/.

Simulink is a high-level implementation of the engineering approach, based on block diagrams, to analyze and design control systems. It is also a powerful modeling and multi-domain simulation and model-based design tool for dynamic systems, which supports hierarchical system-level design, simulation, automatic code generation, and continuous test and verification of embedded systems. Simulink offers a graphical editor, customizable block libraries, and solvers for modeling and simulating dynamic systems. The models may include MATLAB algorithms, and the simulation results may be further processed to MATLAB. Managing projects (files, components, data), connecting to hardware for real-time testing, and deploying the designed system are additional, useful Simulink features. Real-Time Workshop code generation allows to speed up the design and implementation, by generating syntactically and semantically correct code which can be uploaded to the target machine.

MATLAB environment is very suitable for rapid prototyping, seen in a broad sense. This may include not only fully designing and implementing a new control law, testing it on a host computer, and deploying on a target computer but also support for developing and testing new mathematical or control theories and algorithms.

Born around 1980, MATLAB has evolved and improved impressively. Since 2004, two releases have been issued each year. There was a major change of the interface in Release 2012b, visible

both in the core MATLAB "Desktop" and in Simulink. The so-called Toolstrip interface replaces former menus and toolbars and includes tabs which group functionality for common tasks. A gallery of applications from the MATLAB family of products is additionally available and can be extended by the user.

MATLAB supports developing applications with graphical user interface (GUI) features; this itself can be done graphically using GUIDE (GUI development environment). MATLAB has support for object-oriented programming and interfacing with other languages or connecting to similar environments as Maple or Mathematica. When using the command-line interface, MATLAB helps the user, e.g., by showing the arguments of the typed MATLAB functions; also, MATLAB allows execution profiling, for increasing the computational efficiency, and its editor can suggest changes in the user functions (the so-called M-files) for improving the performance.

MATLAB users may upload their own contributions to the MATLAB Central website or may download tools developed by other people. User feedback is used by the MATLAB developers to improve the functionality, reliability, and efficiency of the computations.

Commercial competitors to MATLAB include Mathematica, Maple, and IDL; free open-source alternatives are, e.g., GNU Octave, FreeMat, and Scilab, intended to be mostly compatible with the MATLAB language. For instance, a set of free CACSD tools for GNU Octave version 3.6.0 or beyond has been very recently developed (see http://octave.sourceforge.net/control/). The Octave extension package called *control* is based on the SLICOT Library and includes functionalities for system identification, system analysis, control system design (including H_∞ synthesis), and model reduction, which are the basic steps of the control engineer design workflow.

Mathematica is an interactive environment which supports complete computational workflows, making it suitable for a convenient endeavor from ideas to deployed solutions (see http://www.wolfram.com/mathematica/).

Mathematica offers, e.g., tools for 2D and 3D data and function visualization and animation, numeric and symbolic tools for discrete and continuous calculus, a toolkit for adding user interfaces to applications, control systems libraries, tools for parallel programming, etc. High-performance computing capabilities include the use of packed and sparse arrays, multiple precision arithmetic, automatic multi-threading on multi-core computers (based on processor-specific optimized libraries), hardware accelerators, support for grid technology, and CUDA and OpenCL GPU hardware. Mathematica and SystemModeler (based on Modelica© language) offer numerous built-in functions which allow to design, analyze, and simulate continuous- and discrete-time control systems; simplify models; interactively test controllers; and document the design. Both classical and modern techniques are provided. A powerful symbolic-numeric computation engine and highly efficient numerical algorithms are used. Mathematica allows to define the system models in a more natural form than MATLAB. It can analyze not only numeric systems but also symbolic ones, represented by state-space or transfer-function models. The computational precision and algorithms can be automatically controlled and selected, respectively, and using arbitrary precision arithmetic is possible.

Maple is a computer algebra system, which combines a powerful engine for mathematical calculations with an intuitive user interface (see http://www.maplesoft.com/). Classical mathematical notation can be used, and the interface is customizable. Arbitrary precision numerical computations, as well as symbolic computations, can be performed. The Maple language is provided by a small kernel. NAG Numerical Libraries, ATLAS libraries, and other libraries written in this language are used for numerical calculations. Symbolic expressions are stored as directed acyclic graphs. The latest release, Maple 17, added hundreds of new problem-solving commands and interface enhancements. Many calculations recorded an impressive improvement in efficiency, compared

I

to the previous release. Examples include calculations with complex floating-point numbers and linear algebra operations. It is possible to use multiple cores and CPUs. The parallel memory management has been improved. Maple includes some CACSD tools for linear and nonlinear dynamic systems. For instance, the built-in package DynamicSystems (available since Maple 12 release) covers the analysis of linear time-invariant systems. Numerical solvers for Sylvester and Lyapunov equations have been added to the LinearAlgebra packages in Maple 13, and solvers for algebraic Riccati equations – based on SLICOT Library routines – have been included in Maple 14 (available in multiple precision arithmetic since Maple 15). Moreover, the MapleSim environment, based on Modelica, is dedicated to physical modeling and simulation. Symbolic simplification, numerical solution of the differential-algebraic equations (DAEs), and model post-processing (sensitivity analysis, linearization, parameter optimization, code generation, etc.) can be performed in MapleSim. Its Control Design Toolbox provides solutions for optimal control, Kalman filtering, pole assignment, etc. Bidirectional communication with MATLAB is possible.

MuPAD is another computer algebra system, initially developed by a group at the University of Paderborn, Germany, and then in cooperation with SciFace Software GmbH & Co. KG, company purchased in 2008 by The MathWorks, Inc. MuPAD has been used with Scilab, and now it is available in the Symbolic Math Toolbox. MuPAD is able to operate on formulas symbolically or numerically (with specified accuracy). It offers a programming language allowing object-oriented and functional programming, several packages for linear algebra, differential equations, number theory, and statistics, an interactive graphical system supporting animations and transparent areas in tridimensional images, etc.

LabVIEW (Laboratory Virtual Instrumentation Engineering Workbench), from National Instruments, is an interactive development environment, based on MATRIXx, for a visual programming language mainly used for data

acquisition, instrument control, and industrial automation. Its Control Design and Simulation Module (see http://sine.ni.com/psp/app/doc/p/id/psp-648/lang/en) can be used to build process and controller models using transfer-function, state-space, or zero-pole-gain representations, analyze the open- and closed-loop system behavior, deploy the designed controllers to real-time hardware using built-in functions and LabVIEW Real-Time Module, etc.

Software Tools for CACSD

The software tools for CACSD are formally divided below into computational and support tools. SLICOT Library and Dymola serve as illustrative examples. The support tools can also include computational components.

Computational Tools

The computational tools for CACSD implement the main numerical algorithms of the systems and control theory and should satisfy several strong requirements:

- Reliability or guaranteed accuracy, which implies the use of numerically stable algorithms as much as possible and the estimation of the problem sensitivity (conditioning) and of the results accuracy; backward numerical stability ensures that the computed results are exact for slightly perturbed original data.
- Computational efficiency, which is important for large-scale engineering design problems or for real-time control.
- Robustness, which is mainly ensured by avoiding overflows, harmful underflows, and unacceptable accumulation of rounding-errors; scaling the data may be essential.
- Ease-of-use, achieved by simplified user interface (hiding the details), and default values for algorithmic parameters, such as tolerances.
- Wide scope and rich functionality, which address the range of problems and system representations that can be handled.
- Portability to various platforms, in the sense of functional correctness.
- Reusability, in building several dedicated engineering software systems or environments.

More details are given, e.g., in Van Huffel et al. (2004). An example addressing all these aspects is discussed in what follows.

SLICOT Library Benner et al. (1999) and Van Huffel et al. (2004) is one of the most comprehensive libraries for control theory numerical computations, containing over 500 subroutines which cover system analysis, benchmark and test problems, data analysis, filtering, identification, mathematical routines, some capabilities for nonlinear systems, synthesis, system transformation, and utility routines (see http://www.slicot. org/). The requirements above have been taken into account in the SLICOT Library development. Some of the SLICOT components are used in several interactive environments for CACSD, including MATLAB, Maple, Scilab, and Octave *control* package. The library is still under development. It is worth mentioning the new focus on structure-preserving algorithms, which offer increased accuracy, reliability, and efficiency, in comparison with standard solvers. Many procedures for optimal control and filtering, model reduction, etc., can benefit from using the "structured" solvers. There are also separate SLICOT-based toolboxes for MATLAB (Benner et al. 2010). SLICOT components follow predefined implementation and documentation standards.

SLICOT Library routines, and functions from many interactive environments for CACSD call components from the Basic Linear Algebra Subprograms (BLAS, see Dongarra et al. 1990 and the references therein) and Linear Algebra PACKage (LAPACK, Anderson et al. 1999). This approach enhances portability and efficiency, since optimized BLAS and LAPACK Libraries are provided for major computer platforms.

Support Tools

The support software tools for CACSD offer additional capabilities compared to computational tools. They may include alternative algorithms, symbolic computations (usually, for low-dimensional problems), and extended functionality, e.g., for modeling/simulation of nonlinear systems, code generation, etc. The support tools can be used by software developers of CACSD environments or computational tools

or directly by other users. For instance, symbolic calculations are useful for checking the accuracy of numerical algorithms. The code generation facility offers a safe and convenient support for deploying a design solution to the control hardware. A reference support software tool is briefly presented below.

Dymola (Dynamic modeling laboratory), from Dassault Systemes (see http://www.3ds.com/ products/catia/portfolio/dymola), deals with high-fidelity modeling and simulation of complex systems from various domains, like aerospace, automotive, robotics, process control, and other applications. Compatible and comprehensive model libraries, developed by leading experts, exist for many engineering branches. The users may create their own libraries or adapt existing libraries. This flexibility and openness is provided by the use of the open, object-oriented modeling language Modelica$^{©}$, currently further developed by the Modelica Association.

Equation-oriented models, based on DAEs, and symbolic manipulation are used, stimulating the reuse of components and enhancing the reliability and efficiency of the calculations. This approach enables to simplify generating the equations, which result from interconnecting various subsystems, and to deal with algebraic loops and structurally singular models. Algebraic loops are encountered when some auxiliary variables depend algebraically upon each other in a mutual way (Cellier and Elmqvist 1992). Structural singularities are related to DAE of index higher than 1.

Dymola allows performing hardware-in-the-loop simulation and real-time 3D animation. A model can be built by graphical composition, connecting components from various libraries using simple dragged-and-dropped operations. The parameters a model depends on can be tuned either by *parameter estimation* (also called *model calibration*), which minimizes the error between the physical measurements and simulation results, or by optimization, which minimizes certain performance criteria. Sometimes, e.g., when designing certain controllers, the criteria values are obtained by simulation. Dymola offers also facilities for model management, including

checking, testing, encrypting, or comparing models, and version control.

Summary and Future Directions

The main functional and support facilities offered by interactive environments and software tools for CACSD and reference examples have been presented. Their remarkable evolution during the past decades, combined with the importance of the design solutions they offer, is the strong argument that the CACSD software arsenal will continue to evolve and more reliable, efficient, and powerful systems will come into place. Progress is expected at all levels, including basic algorithms and numerical and symbolic libraries but also command languages, user interfaces, human-machine communication, and associated hardware. Tools for adaptive, nonlinear, and distributed control systems design should be developed and integrated. Artificial intelligence support might be required to add expert capabilities to the forthcoming interactive environments.

Recommended Reading

CACSD is well presented in many textbooks. A very recent one is Chin (2012), which covers modeling, control system design, implementation, and testing, and describes practical applications using MATLAB and Simulink. Many IFAC (International Federation of Automatic Control) and IEEE (Institute for Electrical and Electronics Engineers) international conferences and symposia have been dedicated to CACSD, going back more than two decades. A wealth of material is available, e.g., on IEEE Xplore (ieeexplore.ieee.org), containing the proceedings of many of the IEEE CACSD events. A recent event is the 2011 IEEE International Symposium on CACSD. Similar IEEE events were hold on 2010, 2008, 2006, 2004, 2002, 2000, 1999, 1996, 1994, 1992, and 1989. A new IEEE CACSD Conference, for Systems under Uncertainty, took place in July 2013.

Inventory Theory

Suresh P. Sethi
Jindal School of Management, The University of Texas at Dallas, Richardson, TX, USA

Abstract

This entry is a brief survey of classical inventory models and their extensions in several directions such as world-driven demands, presence of forecast updates, multi-delivery modes and advanced demand information, incomplete inventory information, and decentralized inventory control in the context of supply chain management. Important references are provided. We conclude with suggestions for future research.

Keywords

Base stock policy; EOQ model; Incomplete information; Newsvendor model; (s, S) policy

Introduction

Optimal inventory theory deals with managing stock levels of goods to effectively meet the demand of those goods. Because of the huge amount of capital that is tied up in inventory, its management is critical to the profitability of firms. A systematic analysis of inventory problems began with the development of the classical economic order quantity (EOQ) formula of Ford W. Harris in 1913. A substantial amount of research was reported in 1958 by Kenneth J. Arrow, Samuel Karlin, and Herbert Scarf, and much more has accumulated since then. Books on the topic include Zipkin (2000), Porteus (2002), Axsäter (2006), and Bensoussan (2011).

In this entry, we review single- and multi-period models with deterministic, stochastic, partially observed demand for a single product. In these models, our aim is to decide on the time of the orders and the order quantities. The time

between issuing an order and its receipt is called the lead time. For most of this review, we will assume the lead time to be zero, and the reader can consult the referenced books for nonzero lead time extensions and other topics not covered here.

Deterministic Demand

We will describe two classical models: the EOQ model and the dynamic lot size model.

The EOQ Model

This basic and most important deterministic model is concerned with a product that has a constant demand rate D in continuous time over an infinite horizon. No shortages are allowed. The costs consist of a fixed setup/ordering cost K and a holding cost h per unit of average on-hand stock per unit time. The production/purchase cost per unit time is a sunk cost since there is no choice of a total amount to produce, and hence it can be ignored. Although dynamic, the model can be reduced to a static model by a simple argument of periodicity. Moreover, it is obvious that one should never produce or order except for when the inventory level is zero, and one should order the same lot size Q each time the inventory level reaches zero. Since the average inventory level over time is $Q/2$ and the number of setups is D/Q per unit time, the long-run average cost to be minimized is $KD/Q+hQ/2$. The optimal policy that minimizes this cost, obtained using the first-order condition, is to order the lot size

$$Q = \sqrt{\frac{2KD}{h}} \qquad (1)$$

every time the inventory level reaches zero. Harris (1913) introduced the model. Erlenkotter (1990) provides a historical account of the formula, and Beyer and Sethi (1998) provide a mathematically rigorous proof involving quasi-variational inequalities (QVI) that arise in the course of dealing with continuous-time optimization problems involving fixed costs.

The Dynamic Lot Size Model

This is an analogue of the EOQ model when the demand varies over time. Wagner and Whitin (1958) developed it in the discrete-time finite horizon framework. With $D(t)$ denoting the demand in period t and other costs similar to those in the EOQ model, they showed that there exists an optimal policy in which an order will be issued just as the inventory level reaches zero, except for the first order. This policy is called the zero-inventory policy. With this in hand, the problem reduces to selecting only the order times. This is accomplished by applying a shortest path algorithm. Moreover, there are forward (recursion) procedures for solving the problem.

An important feature of this model is that in most cases, one can detect a *forecast horizon* which essentially separates earlier periods from later ones. More specifically, T is a forecast horizon if the first order in a T horizon problem remains optimal in any finite horizon problem with horizon longer than T, regardless of the demands beyond the period T. For an extensive bibliography of this literature, see Chand et al. (2002).

Stochastic Demand

We shall discuss three classical models and some of their extensions.

The Single-Period Problem: The Newsvendor Model

The problem of a newsvendor is to decide on an order quantity of newspapers to meet a stochastic demand at a minimum cost. If the realized demand is larger than the ordered quantity, it is lost and there is an opportunity loss of c_u (selling price minus purchase cost) for each paper short. On the other hand, for each paper ordered but not sold, there is an opportunity loss of c_o (purchase cost plus holding cost). The newsvendor conceptualizes the decision by each additional paper as a separate marginal contribution. The first is almost certain to be sold. Each additional paper is less likely to be sold than the previous one. Thus, each additional paper will be worth somewhat

less, and the marginal paper at the optimum should be worth exactly zero. Thus, c_u times the probability of selling the marginal paper minus c_o times the probability of not selling it should equal zero. Now, if F denotes the cumulative probability distribution function of the demand D, then clearly the optimal order quantity Q satisfies $c_o \cdot F(Q) - c_u \cdot (1 - F(Q)) = 0$, which gives us the famous newsvendor formula for the optimal order quantity

$$Q = F^{-1}\left(\frac{c_u}{c_u + c_o}\right), \qquad (2)$$

where $c_u / (c_u + c_o)$ is known as the critical fractile.

If p denotes the unit sale price, c the unit cost, and h the holding cost per unit per unit time, then $c_u = p - c$ and $c_o = c + h$, and therefore, the critical fractile can be expressed as $(p - c) / (p + h)$. An extension of the newsvendor formula to allow for a unit cost g of lost goodwill and a unit salvage value s received at the end of the period for each unit not sold is immediate. If we let $\alpha > 0$ denote the periodic discount factor, then $c_u = p + g - c$ and $c_o = c + h - \alpha s$ and the critical fractile becomes $(p + g - c) / (p + g + h - \alpha s)$, and therefore,

$$Q = F^{-1}\left(\frac{p + g - c}{p + g + h - \alpha s}\right). \qquad (3)$$

The newsvendor model has been used extensively in the context of supply chain management with multiple agents maximizing their individual objectives. In this case, inefficiencies arise due to double marginalization. Then, a question of appropriate contracts that can lead to the first-best solution, or coordinate the supply chain, becomes important. Cachon (2003) surveys this literature.

Multi-period Inventory Models: No Fixed Cost

The newsvendor model is a single-period model, and its multi-period generalization requires that the inventory not sold in a period is carried over to the next period. This results in the multi-period inventory model with lost sales. It is assumed

that demand in each period is independent and identically distributed (i.i.d.) with F denoting its cumulative probability distribution function. A rigorous analysis requires the method of dynamic programming, and it shows that there is a stock level S_t called *base stock* in period t, that we would ideally like to have at the beginning of period t. Thus, the optimal policy in period t, called *the base stock policy*, is to order

$$Q_t(x) = \begin{cases} S_t - x & \text{if } x < S_t, \\ 0 & \text{if } x \geq S_t. \end{cases} \tag{4}$$

In the special case when the terminal salvage value of an item is exactly equal to its cost c, it is possible to come up with the optimal policy using intuition. Since we do not need to salvage unused items in the multi-period setting, one can argue that an item carried over to the next period is worth its purchase cost c. Therefore, its presence means that the next period will need to order one less and thus save an amount c. In the last period, when there is no next period, our terminal salvage value assumption also guarantees a leftover item's worth to be also c. Thus, we can modify (3) and obtain a stationary base stock level

$$S = F^{-1} \left(\frac{p + g - c}{(p + g - c) + (c + h - \alpha c)} \right)$$
$$= F^{-1} \left(\frac{p + g - c}{p + g + h - \alpha c} \right) \tag{5}$$

for each period t.

Thus, the elimination of the endgame effect delivers us a *myopic policy*, a policy optimal in the single-period case to be also optimal in the dynamic multi-period setting. A more general concept than the optimality of a myopic policy is that of the forecast horizon mentioned earlier in the context of the dynamic lot size model.

Sometimes, when the demand exceeds the on-hand inventory in the period, the demand is not lost but backlogged. In this case, each unit of backlogged demand is satisfied in the next period, and unit revenue p is recovered, but a unit backlogging cost b is incurred, due to expediting, special handling, delayed receipt of revenue, and loss of goodwill. Thus, $c_u = b - (1 - \alpha)c$,

where the second term represents the savings due to postponing the purchase of the backlogged demand unit by one period, and $c_o = c + h - \alpha c$ as in (4). This gives us the base stock level

$$S = F^{-1} \left(\frac{b - (1 - \alpha)c}{b + h} \right), \tag{6}$$

which can be used in (5) to give the optimal policy.

Sometimes it is possible to have multiple delivery modes such as fast, regular, and slow as well as demand forecast updates. Then, at the beginning of each period, on-hand inventory and demand information are updated. At the same time, decisions on how much to order using each of the modes are made. Fast, regular, and slow orders are delivered at the ends of the current, the next, and one beyond the next periods, respectively. In such models, a modified base stock policy is optimal only for the two fastest modes. For details and further generalization, see Sethi et al. (2005).

An important extension includes serial inventory systems where stage 1 receives supplies from an outside source and each downstream stage receives supplies from its immediate upstream stage. Clark and Scarf (1960) introduced the notion of the echelon inventory position at a stage to consist of the stock at that stage plus stock in transit to that stage plus all downstream stock minus the amount backlogged at the final stage. Then, the optimal ordering policy at each stage is given by an echelon base stock policy with respect to the echelon inventory position at that stage. It is known that assembly systems can be reduced to a serial system. Details can be found in Zipkin (2000).

Multi-period Inventory Models: Fixed Cost

When there is a fixed cost of ordering, it is clear that it would not be reasonable to follow the base stock policy when the inventory level is not much below the base stock level. Indeed, Scarf (1960) proved that there are numbers s_t and S_t, $s_t < S_t$, for period t such that the optimal policy in period t is to order

$$Q_t(x) = \begin{cases} S_t - x & \text{if } x \leq s_t \\ 0 & \text{if } x > s_t. \end{cases} \tag{7}$$

Such a policy is famously known as an (s, S) policy.

When the demands are not i.i.d., the model has been extended to Markovian demands. In this case, there is an exogenous Markov process, and the distribution of the demand in each period depends on the state of the Markov process, called the demand state, in that period. It can be shown that the optimal policy in period t is (s_t^i, S_t^i), where i denotes the demand state in the period. Such a policy is also called a state-dependent (s, S) policy. Further details are available in Beyer et al. (2010). Recent advances in information technology have allowed managers to obtain advance demand information in addition to forecast updates. In such cases, a state-dependent (s, S) policy can be shown to be optimal. For details, refer to Ozer (2011).

The Continuous-Time Model: Fixed Cost

The marriage of the two classical results (1) and (7) is accomplished by Presman and Sethi (2006) in a continuous-time stochastic inventory model involving a demand that is the sum of a constant demand rate and a compound Poisson process. The optimal policies that minimize a discounted cost or the long-run average cost are both of (s, S) type. The (s, S) policy minimizing the long-run average cost reduces to the EOQ formula when the intensity of the compound Poisson process is set to zero. And when the constant demand component vanishes, the model reduces to the continuous-review stochastic inventory model with fixed cost and compound Poisson demand.

Incomplete Inventory Information Models (i3)

A critical assumption in the vast inventory theory literature has been that the level of inventory at any given time is fully observed. The celebrated results (1) and (7) have been obtained under the assumption of full observation. Yet the inventory level is often not fully observed in practice, for a variety of reasons such as replenishment errors, employee theft, customer shoplifting, improper handling and damaging of merchandise, misplaced inventories, uncertain yield, imperfect inventory audits, and incorrect recording of sales. In such an environment of incomplete information, inventories are known to be partially observed and most of the well-known inventory policies including (1) and (7) are not even admissible, let alone optimal. In such cases, Bensoussan et al. (2010) show that the dynamic programming equation can be written in terms of the unnormalized conditional probability of the current inventory level given past observations, referred to as signals, instead of just the inventory level in the full observation case. Furthermore, one can write the evolution of the conditional probability in terms of its current value, the current order, and the current observation. However, there are no longer simple optimal policies except in cases of information delay reported in Bensoussan et al. (2009) where modified base stock and (s, S) policies are shown to be optimal.

Summary and Future Directions

We briefly describe some classical results in inventory theory. These are based on full observation. Some recent work on inventory models under incomplete information is reported. This work leads to a number of new research directions, both theoretical and empirical as reported in Sethi (2010). It would be of much interest to know the industries where the i3 problem is serious enough to warrant the difficult mathematical analysis required. Furthermore, how are the observed signals related to the inventory level? It is also clear from the reviewed literature that there are no simple optimal policies for most i3 problems, so it would be important to develop efficient computational procedures to obtain optimal solutions or to specify a class of simple implementable policies and optimize within this class. An important benefit of solving i3 problems optimally is the provision of an economic justification for technologies such as RFID that may reduce inaccuracies in inventory observations.

Another area of research would be to study multi-period multi-agent supply chains with a stochastic inventory dynamics. While these can be formulated as dynamic games, there are a number of equilibrium concepts to deal with,

depending on the information the agents have. Some of them are time consistent or subgame perfect and some are not. Regardless, there are inefficiencies that arise from these decentralized game settings, and developing contracts for coordinating dynamic supply chains remains a wide open topic of research.

Investment-Consumption Modeling

L.C.G. Rogers
University of Cambridge, Cambridge, UK

Abstract

The simplest investment-consumption problem is the celebrated example of Robert Merton (J Econ Theory 3(4):373-413, 1971). This survey shows three different ways of solving the problem, each of which is a valuable solution method for more complicated versions of the question.

Keywords

Budget constraint; Hamilton-Jacobi-Bellman (HJB) equation; Merton problem; Value function

Introduction

Consider an investor in a market with a riskless bank account accruing continuously compounded

interest at rate r_t, and with a single risky asset whose price S_t at time t evolves as

$$dS_t = S_t(\sigma_t dW_t + \mu_t dt), \qquad (1)$$

where W is a standard Brownian motion, and σ and μ are processes previsible with respect to the filtration of W. The investor starts with initial wealth w_0 and chooses the rate c_t of consuming, and the wealth θ_t to invest in the risky asset, so that his overall wealth evolves as

$$dw_t = \theta_t(\sigma_t dW_t + \mu_t dt) + r_t(w_t - \theta_t)dt - c_t dt \tag{2}$$

$$= r_t w_t\, dt + \theta_t\{\sigma_t dW_t + (\mu_t - r_t)dt\} - c_t\, dt. \tag{3}$$

For convenience, we assume that σ, σ^{-1}, and μ are bounded. See Rogers and Williams (2000a,b) for background information on stochastic processes. The three terms in (2) have natural interpretations: The first expresses the evolution of the wealth invested in the stock, the second the interest accruing on the wealth $(w - \theta)$ invested in the bank account, and the third is the cash being withdrawn for consumption.

To avoid so-called doubling strategies, we insist that the wealth process so generated by the controls (c, θ) must remain bounded below in some suitable way, which here is just the condition $w_t \geq 0$ for all $t \geq 0$; any (c, θ) satisfying this condition will be called *admissible*. The set of admissible (c, θ) will be denoted $\mathcal{A}(w_0)$, a notation which makes explicit the dependence on the investor's initial wealth.

The investor's objective is taken to be to obtain

$$V(w_0) \equiv \sup_{(c,\theta)\in\mathcal{A}(w_0)} E\left[\int_0^\infty e^{-\rho t} U(c_t)\, dt\right] \tag{4}$$

for some constant $\rho > 0$. The problem cannot be solved explicitly at this level of generality, but if we take some special cases, we are able to illustrate the main methods used to attack it. Many other objectives with various different constraints can be handled by similar techniques: see Rogers (2013) for a wide range of examples.

The Main Techniques

We present here three important techniques for solving such problems: the value function approach; the use of dual variables; and the use of martingale representation. The first two methods only work if the problem is Markovian; the third only works if the market is complete. There is a further method, the Pontryagin-Lagrange approach; see Sect. 1.5 in Rogers (2013). While this is a quite general approach, we can only expect explicit solutions when further structure is available.

The Value Function Approach

To illustrate this, we focus on the original Merton problem (Merton 1971), where σ and μ are both constant, and the utility U is constant relative risk aversion (CRRA):

$$U'(x) = x^{-R} \qquad (x > 0) \tag{5}$$

for some $R > 0$ different from 1. The case $R = 1$ corresponds to logarithmic utility, and can be solved by similar methods. Perhaps the best starting point is the *Davis-Varaiya Martingale Principle of Optimal Control (MPOC)*: The process $Y_t = e^{-\rho t} V(w_t) + \int_0^t e^{-\rho s} U(c_s)\, ds$ is a supermartingale under any control, and a martingale under optimal control. If we use Itô's formula, we find that

$$e^{\rho t} dY_t = -\rho V(w_t)dt + V'(w_t)dw_t$$
$$+ \tfrac{1}{2}\sigma^2\theta_t^2 V''(w_t)dt + U(c_t)dt$$
$$\doteq [-\rho V + \{\theta_t(\mu - r) - c_t + r\}V'$$
$$+ \tfrac{1}{2}\sigma^2\theta_t^2 V'' + U(c_t)]\, dt, \tag{6}$$

where the symbol $\doteq$ denotes that the two sides differ by a (local) martingale. If the MPOC is to hold, then we expect that the drift in dY should be non-positive under any control, and equal to zero under optimal control. We simply assume for now that local martingales are martingales; this is of course not true in general, and is a point that needs to be handled carefully in a rigorous proof. Directly from (6), we then deduce the

Hamilton-Jacobi-Bellman (HJB) equations for this problem:

$$0 = \sup_{c,\theta}[-\rho V + \{\theta(\mu - r) - c + r\}V' + \tfrac{1}{2}\sigma^2\theta^2 V'' + U(c)]. \quad (7)$$

Write $\tilde{U}(y) \equiv \sup \{U(x) - xy\}$ for the convex dual of U, which in this case has the explicit form

$$\tilde{U}(y) = -\frac{y^{1-R'}}{1-R'} \quad (8)$$

with $R' \equiv 1/R$. We are then able to perform the optimizations in (7) quite explicitly to obtain

$$0 = -\rho V + rV' + \tilde{U}(V') - \tfrac{1}{2}\kappa^2 \frac{(V')^2}{V''} \quad (9)$$

where

$$\kappa \equiv \frac{\mu - r}{\sigma}. \quad (10)$$

Nonlinear PDEs arising from stochastic optimal control problems are not in general easy to solve, but (9) is tractable in this special setting, because the assumed CRRA form of U allows us to deduce by a scaling argument that $V(w) \propto w^{1-R} \propto U(w)$, and we find that

$$V(w) = \gamma_M^{-R} U(w), \quad (11)$$

where

$$R\gamma_M = \rho + (R-1)(r + \tfrac{1}{2}\kappa^2/R). \quad (12)$$

The optimal investment and consumption behavior is easily deduced from the optimal choices which took us from (7) to (9). After some calculations, we discover that

$$\theta_t^* = \pi_M w_t \equiv \frac{\mu - r}{\sigma^2 R} w_t, \qquad c_t^* = \gamma_M w_t \quad (13)$$

specifies the optimal investment/consumption behavior in this example. (The positivity of γ_M is necessary and sufficient for the problem to be well posed; see Sect. 1.6 in Rogers (2013)). Unsurprisingly, the optimal solution scales linearly with wealth.

Dual Variables

We illustrate the use of dual variables in the constant-coefficient case of the previous section, except that we no longer suppose the special form (5) for U. The analysis runs as before all the way to (9), but now the convex dual $\tilde{U}$ is not simply given by (8). Although it is not now possible to guess and verify, there is a simple transformation which reduces the nonlinear ODE (9) to something we can easily handle. We introduce the new variable $z > 0$ related to w by $z = V'(w)$, and define a function J by

$$J(z) = V(w) - wz. \quad (14)$$

Simple calculus gives us $J' = -w$, $J'' = -1/V''$, so that the HJB equation (9) transforms into

$$0 = \tilde{U}(z) - \rho J(z) + (\rho - r)zJ'(z) + \tfrac{1}{2}\kappa^2 z^2 J''(z), \quad (15)$$

which is now a second-order *linear* ODE, which can be solved by traditional methods; see Sect. 1.3 of Rogers (2013) for more details.

Use of Martingale Representation

This time, we shall suppose that the coefficients μ_t, r_t, and σ_t in the wealth evolution (3) are general previsible processes; to keep things simpler, we shall suppose that μ, r, and σ^{-1} are all bounded previsible processes. The Markovian nature of the problem which allowed us to find the HJB equation in the first two cases is now destroyed, and a completely different method is needed. The way in is to define a positive semimartingale ζ by

$$d\zeta_t = \zeta_t(-r_t dt - \kappa_t dW_t), \qquad \zeta_0 = 1 \quad (16)$$

where $\kappa_t = (\mu_t - r_t)/\sigma_t$ is a previsible process, bounded by hypothesis. This process, called the *state-price density process*, or the *pricing kernel*, has the property that if w evolves as (3), then $M_t \equiv \zeta_t w_t + \int_0^t \zeta_s c_s \, ds$ is a positive local martingale.

Since positive local martingales are super-martingales, we deduce from this that

$$M_0 = w_0 \geq E\left[\int_0^\infty \zeta_s c_s \, ds\right]. \qquad (17)$$

Thus, for any $(c, \theta) \in \mathcal{A}(w_0)$, the budget constraint (17) must hold. So the solution method here is to maximize the objective (4) subject to the constraint (17). Absorbing the constraint with a Lagrange multiplier λ, we find the unconstrained optimization problem

$$\sup E\left[\int_0^\infty \{e^{-\rho s} U(c_s) - \lambda \zeta_s c_s\} \, ds\right] + \lambda w_0 \qquad (18)$$

whose optimal solution is given by

$$e^{-\rho s} U'(c_s) = \lambda \zeta_s, \qquad (19)$$

and this determines the optimal c, up to knowledge of the Lagrange multiplier λ, whose value is fixed by matching the budget constraint (17) with equality.

Of course, the missing logical piece of this argument is that if we are given some $c \geq 0$ satisfying the budget constraint, is there necessarily some θ such that the pair (c, θ) is admissible for initial wealth w_0? In this setting, this can be shown to follow from the Brownian integral representation theorem, since we are in a complete market; however, in a multidimensional setting, this can fail, and then the problem is effectively insoluble.

Summary and Future Directions

This brief survey states some of the main ideas of consumption-investment optimization, and sketches some of the methods in common use. Explicit solutions are rare, and much of the interest of the subject focuses on efficient numerical schemes, particularly when the dimension of the problem is large. A further area of interest is in continuous-time principal-agent problems; Cvitanic and Zhang (2012) is a recent account of some of the methods of this subject, but it has to be said that the theory of such problems is much less complete than the simple single-agent optimization problems discussed here.

Iterative Learning Control

David H. Owens
University of Sheffield, Sheffield, UK

Synonyms

ILC

Abstract

Iterative learning control addresses tracking control where the repetition of a task allows improved tracking accuracy from task to task. The area inherits the analysis and design issues of classical control but adds convergence conditions

for task to task learning, the need for acceptable task-to-task performance and the implications of modeling errors for task-to-task robustness.

Keywords

Adaptation; Optimization; Repetition; Robustness

Introduction

Iterative learning control (ILC) is relevant to trajectory tracking control problems on a finite interval $[0, T]$ (Ahn et al. 2007b; Bien and Xu 1998; Chen and Wen 1999). It has close links to multipass process theory (Edwards and Owens 1982) and repetitive control (Rogers et al. 2007) plus conceptual links to adaptive control. It focuses on problems where the repetition of a specified task creates the possibility of improving tracking accuracy from task to task and, in principle, reducing the tracking error to exactly zero. The iterative nature of the control schemes proposed, the use of past executions of the control to update/improve control action, and the asymptotic learning of the required control signals put the topic in the area of adaptive control, although other areas of study are reflected in its methodologies.

Application areas include robotic assembly (Arimoto et al. 1984), electromechanical test systems (Daley et al. 2007), and medical rehabilitation robotics (Rogers et al. 2010). For example, consider a manufacturing robot required to undertake an indefinite number of identical tasks (such as "pick and place" of components) specified by a spatial trajectory on a defined time interval. The problem is two-dimensional. More precisely, the controlled system evolves with *two* variables, namely, time $t \in [0, T]$ (elapsed in each iteration) and iteration index $k \geq 0$. Data consists of signals $f_k(t)$ denoting the value of the signal f at time t on iteration k. The conceptual algorithm used is:

Step one: (Preconditioning) Implement loop controllers to condition plant dynamics.

Step two: (Initialization) Given a demand signal $r(t)$, $t \in [0, T]$, choose an initial input $u_0(t)$, $t \in [0, T]$ and set $k = 0$.

Step three: (Response measurement) Return the plant to a defined initial state. Find the output response y_k to the input u_k. Construct the tracking error $e_k = r - y_k$. Store data.

Step four: (Input signal update) Use past records of inputs used and tracking errors generated to construct a new input $u_{k+1}(t)$, $t \in [0, T]$ to be used to improve tracking accuracy on the next trial.

Step five: (Termination/task repetition) Either terminate the sequence or increase k by unity and return to step 3.

It is the updating of the input signal based on observation that provides the conceptual link to adaptive control. ILC *causality* defines *"past data"* at time t on iteration k as data on the interval $[0, t]$ on that iteration plus all data on $[0, T]$ on all previous iterations. Feedback plus feedforward control normally contains feedforward transfer of information from past iterations to the current iteration.

Modeling Issues

Design approaches have been model-based. Most nonlinear problems assume nonlinear state space models relating the $\ell \times 1$ input vector $u(t)$ to the $m \times 1$ output vector $y(t)$ via an $n \times 1$ state vector $x(t)$ as follows:

$$\dot{x}(t) = f(x(t), u(t)), \quad y(t) = h(x(t), u(t)),$$

where $t \in [0, T]$, $x(0) = x_0$ and f and h are vector-valued functions. The discrete time (sample data) version replaces derivatives by a forward shift, where t is now a sample counter, $0 \leq t \leq N$ (the index of the last sample). The continuous time linear model is

$$\dot{x}(t) = Ax(t) + Bu(t), \quad y(t) = Cx(t) + Du(t)$$

with an analogous model for discrete systems. In both cases, the matrices A, B, C, D are constant or time varying of appropriate dimension.

Nonlinear systems present the greatest technical challenge. Linear system's challenges are greater for the time-varying, continuous time case. The simplest linear case of discrete time, time-invariant systems can be described by a matrix relationship

$$y = Gu + d \qquad (1)$$

where y denotes the $m(N + 1) \times 1$ "supervector" generated by the time series $y(0), y(1), \ldots, y(N)$ and the construction $y = \left[y^T(0), y^T(1), \ldots, y^T(N) \right]^T$, the supervector u is generated, similarly, by the time series $u(0), u(1), \ldots, u(N)$, and d is generated by the times series $Cx_0, CAx_0, \ldots, CA^N x_0$. The matrix G has the lower block triangular structure

$$G = \begin{bmatrix} D & 0 & 0 \cdots 0 \\ CB & D & 0 \cdots 0 \\ CAB & CB & D \cdots 0 \\ \vdots & & \\ CA^{N-1}B & CA^{N-2}B & \cdots D \end{bmatrix}$$

defined in terms of the Markov parameter matrices $D, CB, CAB, \ldots$ of the plant. This structure has led to a focus on the discrete time, time-invariant case, and exploitation of matrix algebra techniques.

More generally, $G : \mathcal{U} \to \mathcal{Y}$ can be a bounded linear operator between suitable signal spaces $\mathcal{U}$ and $\mathcal{Y}$. Taking G as a convolution operator, the representation (1) also applies to time-varying continuous time and discrete time systems. The representation also applies to differential-delay systems, coupled algebraic and differential systems, multi-rate systems, and other situations of interest.

Formal Design Objectives

Problem Statement: *Given a reference signal $r \in \mathcal{Y}$ and an initial input signal $u_0 \in \mathcal{U}$, construct a causal control update rule/algorithm*

$$u_{k+1} = \psi_k(e_{k+1}, e_k, \ldots, e_0, u_k, u_{k-1}, \ldots, u_0)$$

that ensures that $\lim_{k \to \infty} e_k = 0$ (convergence) in the norm topology of $\mathcal{Y}$.

The update rule $\psi_k(\cdot)$ represents the simple idea of expressing u_{k+1} in terms of past data. A general linear "high-order" rule is

$$u_{k+1} = \sum_{j=0}^{k} W_j u_{k-j} + \sum_{j=0}^{k+1} K_j e_{k+1-j} \qquad (2)$$

with bounded linear operators $W_j : \mathcal{U} \to \mathcal{U}$ and $K_j : \mathcal{Y} \to \mathcal{U}$, regarded as compensation elements and/or filters to condition the signals. Typically $K_j = 0$ (resp. $W_j = 0$) for $j > M_e$ (resp. $j > M_u$). A simple structure is

$$u_{k+1} = W_0 u_k + K_0 e_{k+1} + K_1 e_k \qquad (3)$$

Assuming that G and W_0 commute (i.e., $GW_0 = W_0 G$), the resultant error evolution takes the form

$$e_{k+1} = (I + GK_0)^{-1}(W_0 - GK_1)e_k \\ + (I + GK_0)^{-1}(I - W_0)(r - d)$$

ROBUST ILC: *An ILC algorithm is said to be robust if convergence is retained in the presence of a defined class of modeling errors.*

Results from multipass systems theory (Edwards and Owens 1982) indicate robust convergence of the sequence $\{e_k\}_{k \geq o}$ to a limit $e_\infty \in \mathcal{Y}$ (in the presence of small modeling errors) if the spectral radius condition

$$r[(I + GK_0)^{-1}(W_0 - GK_1)] < 1 \qquad (4)$$

is satisfied where $r[\cdot]$ denotes the spectral radius of its argument. However, the desired condition $e_\infty = 0$ is true only if $W_0 = I$. For a given r, it may be possible to retain the benefits of choosing $W_0 \neq I$ and still ensure that e_∞ is sufficiently small for the application in mind, e.g., by limiting limit errors to a high-frequency band. This and other spectral radius conditions form the underlying convergence condition when choosing controller elements but are rarely computed. The simplest algorithm using eigenvalue

computation for a linear discrete time system defines the *relative degree* to be $k^* = 0$ if $D \neq 0$ and the smallest integer k such that $CA^{k-1}B \neq 0$ otherwise. Replacing $\mathcal{Y}$ by the range of G; choosing $W_0 = I, K_0 = 0$, and $K_1 = I$; and supposing that $k^* \geq 1$, the Arimoto input update rule $u_{k+1}(t) = u_k(t) + e_k(t + k^*)$, $0 \leq t \leq N + 1 - k^*$ provides robust convergence if, and only if, $r[I - CA^{k^*-1}B] < 1$. It does not imply that the error signal necessarily improves each iteration. Errors can reach very high values before finally converging to zero. However, if (4) is replaced by the operator norm condition

$$\|(I + GK_0)^{-1}(W_0 - GK_1)\| < 1, \quad \text{then (5)}$$

$\{\|e_k - e_\infty\|_Q\}_{k \geq 0}$ monotonically decreases to zero.

The spectral radius condition throws light on the nature of ILC robustness. Choosing, for simplicity, $K_0 = 0$ and $W_0 = I$, the requirement that $r[I - GK_1] < 1$ will be satisfied by a wide range of processes G, namely those for which the eigenvalues of $I - GK_1$ lie in the open unit circle of the complex plane. Translating this requirement into useful robustness tests may not be easy in general. The discussion does however show that the behavior of GK_1 must be "sign-definite" to some extent as, if $r[I - GK_1] < 1$, then $r[I - (-G)K_1] > 1$, i.e., replacing the plant by $-G$ (no matter how small) will inevitably produce non-convergent behavior. A more detailed characterization of this property is possible for inverse model ILC.

Inverse Model-Based Iteration

If a linear system G has a well-defined inverse model G^{-1}, then the required input signal is $u_\infty = G^{-1}(r - d)$. The simple update rule

$$u_{k+1} = u_k + \beta G^{-1} e_k, \quad (6)$$

where β is a *learning gain*, produces the dynamics

$$e_{k+1} = (1 - \beta)e_k \quad \text{or} \quad e_{k+1} = (1 - \beta)^k e_0,$$

proving that zero error is attainable with added flexibility in convergence rate control by choosing $\beta \in (0, 2)$. Errors in the system model used in (6) are an issue. Insight into this problem has been obtained for single-input, single-output discrete time systems with multiplicative plant uncertainty U as retention of monotonic convergence is ensured (Owens and Chu 2012) by a frequency domain condition

$$|\frac{1}{\beta} - U(e^{i\theta})| < \frac{1}{\beta}, \text{ for all } \theta \in [0, 2\pi] \quad (7)$$

that illustrates a number of general empirical rules for ILC robust design. The first is that a small learning gain (and hence small input update changes and slow convergence) will tend to increase robustness and, hence, that it is *necessary* that multiplicative uncertainties satisfy some form of strict positive real condition which, for (6), is

$$\text{Re}\left[U(e^{i\theta})\right] > 0, \quad \text{for all } \theta \in [0, 2\pi], \quad (8)$$

a condition that limits high-frequency roll-off error and constrains phase errors to the range $(-\frac{\pi}{2}, \frac{\pi}{2})$. The second observation is that if G is non-minimum phase, the inverse G^{-1} is unstable, a situation that cannot be tolerated in practice.

Optimization-Based Iteration

Design criteria can be strengthened by a monotonicity requirement. Measuring error magnitude by a norm $\|e\|_Q$ on $\mathcal{Y}$, such as the weighted mean square error (with Q symmetric, positive definite)

$$\|e\|_Q = \sqrt{\int_0^T e^T(t)Qe(t)dt},$$

then the condition $\|e_{k+1}\|_Q < \|e_k\|_Q$ for all $k \geq 0$ provides a performance improvement from iteration to iteration. This idea leads to a number of design approaches, Owens and Daley (2008) and Ahn et al. (2007b) (which also examines aspects of robustness).

Function/Time Series Optimization

Norm optimal ILC (NOILC) (Owens and Daley 2008) guarantees monotonicity and convergence to $e_\infty = 0$ by computing u_{k+1} to minimize an objective function

$$J(u) = \|e\|_Q^2 + \|u - u_k\|_R^2,$$

subject to plant dynamics. For linear models (1),

$$u_{k+1} = u_k + G^* e_{k+1}$$

where $G^* : \mathcal{Y} \to \mathcal{U}$ is the adjoint operator of G. For continuous or discrete time linear state space models, the problem is a classical optimal tracking problem with a solution with online state feedback and a feedforward term generated offline by simulation of an "adjoint" model. Reducing R in J leads to faster convergence rates, but the presence of non-minimum-phase zeros has a negative effect on convergence (Owens and Chu 2010). Monotonicity and convergence to zero is retained, but, after an initial fall, the error norm then reduces infinitesimally each iteration producing the practical effect of limited error reductions over finite iteration horizons. Rules exist (Owens and Chu 2010) to minimize the effect by choice of u_0 and r.

Related Linear NOILC Problems

If $\mathcal{Y}$ and $\mathcal{U}$ are real Hilbert spaces, geometrical arguments can be used to generate algorithms extending the NOILC algorithm to include (Owens and Daley 2008) acceleration mechanisms, predictive control, and the inclusion of input signal constraints. They also allow more flexibility in the form and specification of the task. In the intermediate point NOILC problem (denoted IPNOILC), the task requirement is that the output signal $y(t)$, $0 \le t \le T$ takes specified values $r(t_1), r(t_2), \ldots, r(t_M)$ as it passes through the M *intermediate points* $0 < t_1 < t_2 < \cdots < t_M$. The precise nature of the trajectory between points is of secondary importance. Again, the solution, for linear state space systems, can be constructed from Riccati equation-based feedback rules combined with "jump" conditions and feedforward control signals computed off-line.

The IPNOILC solution is nonunique, and the remaining degrees of freedom can be used to satisfy other design objectives. Switching algorithms (Owens et al. 2013) converge to a solution of the problem while simultaneously minimizing an auxiliary criterion

$$J_{\mathrm{aux}}(u) = \|z - z_0\|_{\tilde{Q}}^2 + \|u - u_0\|_R^2.$$

Auxiliary optimization is a tool for shaping the solution of the IPNOILC problem. The auxiliary variable z could be internal states whose behavior is important to plant operation or simply defined by the output, e.g., $z = \ddot{y}$ which, if small, might reduce input "forces" and hence actuator activity.

Parameter Optimization

NOILC can be simplified by reducing the degrees of freedom defining control action to a small number of control law parameters. For a discrete system (1), a general update rule is

$$u_{k+1} = u_k + \Gamma(\beta_{k+1})e_k, \ \ k \ge 0 \ .$$

Here the matrix $\Gamma(\beta)$ is linear in the $p \times 1$ parameter vector β with $\Gamma(0) = 0$. Under these conditions $\Gamma(\beta)e = F(e)\beta$ where the matrix $F(e)$ is linear in e with $F(0) = 0$. Examples of useful parameterizations include inverse model control (Owens et al. 2012).

Monotonicity of the error norm is ensured by choosing the parameter vector β_{k+1} to minimize

$$J(\beta) = \|e\|_Q^2 + \beta^T W_{k+1} \beta$$

subject to the dynamic constraint (1). Each $p \times p$ weighting matrix W_{k+1} is symmetric, positive definite, and may be iteration dependent. The algorithm creates a nonlinear ILC law providing a link between parameter evolution, past errors, and the choice of weight W_{k+1}.

Summary and Future Directions

The basic structure of ILC is now well understood with a number of algorithms available with known convergence properties and empirical

links between parameter choice and convergence rates (Ahn et al. 2007a; Bristow et al. 2006; Owens and Daley 2008; Wang et al. 2009; Xu 2011). Optimization-based algorithms provide a structured approach to convergence and have a familiar quadratic optimal control structure. Despite the practical benefits of monotonic error norms, this approach underlines the difficulties induced by non-minimum-phase (NMP) properties of the plant. Operator representations extend this theory to include more general problems such as the intermediate point tracking problem and, where solutions are non-unique, can be converted into iterative algorithms that inherit the properties of NOILC but converge to a solution that also minimizes an auxiliary optimization criterion.

Many of the challenges addressed by NOILC are inherited by other algorithms, many of which mimic established control design paradigms. For example, the commonly used PD update law

$$u_{k+1}(t) = u_k(t) + K_1 e_k(t) + K_2 \dot{e}_k(t)$$

can produce convergence by suitable choice of K_1 and K_2. Proofs of convergence are typically based on spectral radius conditions similar to (4) for linear systems or on techniques such as contraction mapping (fixed point) theorems (Xu 2011) for nonlinear systems. The nonlinear case generally suggests *local* convergence conditions dependent on growth conditions on the nonlinearity. They typically cannot be checked in practice but do link convergence to simple, empirical, gain selection rules.

ILC, as a topic, is a very large area of study. Survey papers indicate that progress has been made in a number of other areas including adaptive ILC, the use of intelligent control ideas of fuzzy logic and neural networks-based control structures, $2D$ systems theory, and mathematical studies of fractional order control laws (Chen et al. 2013). The further development of ILC from its current strong base will draw extensively from classical control knowledge but relies on the three aspects of *plant modeling*, *control design*, and *coping with uncertainty*. Issues central to medium-term success include:

1. Extending current ILC knowledge to other classes of model needed for applications.
2. Integration of online data-based modeling into ILC schemes to enhance adaptive control options.
3. Ensuring the property of error monotonicity or characterizing any non-monotonicity to be expected.
4. The construction of robustness tests and using the ideas in new robust design methodologies.
5. Providing a better understanding of the effect of noise and disturbances on algorithm performance.
6. Extending the range of tasks to include, for example, different challenges for different outputs on different subintervals of $[0, T]$.
7. Creating design tools for nonlinear plant that ensure convergence and a degree of robustness but, in particular, provide some control of internal plant states that may be subject to dynamical constraints.

Kalman Filters

Frederick E. Daum
Raytheon Company, Woburn, MA, USA

Abstract

The Kalman filter is a very useful algorithm for linear Gaussian estimation problems. It is extremely popular and robust in practical applications. The algorithm is easy to code and test. There are many reasons for the popularity of the Kalman filter in the real world, including stability and generality and simplicity. Moreover, the real-time computational complexity is very reasonable for high-dimensional problems. In particular, the computational complexity scales as the cube of the dimension of the state vector.

Description of Kalman Filter

The Kalman filter is an algorithm that computes the best estimate of the state vector of a linear dynamical system given discrete time measurements of a linear function of the state vector corrupted by additive white Gaussian noise. The Kalman filter also quantifies the uncertainty in its estimate of the state vector, using the covariance matrix of estimation errors. The detailed equations of the Kalman filter algorithm and the problem that it solves are given in Gelb et al. (1974), which is the most accessible but thorough book on Kalman filters. The linear dynamical system can be time varying, but its parameters must be known exactly. The measurements can be made at arbitrary (nonuniform) discrete times, but these times must be known exactly. Likewise, the covariance matrices of the measurement errors and the process noise can be arbitrary and time varying, but the numerical values of these covariance matrices must be known exactly. Also, the initial uncertainty in the state vector must be Gaussian and the mean and covariance matrix can be arbitrary, but these must be known exactly. There is a very powerful theory of Kalman filter stability due to Kalman (1963), which guarantees that the Kalman filter is stable under very mild technical assumptions which can always be satisfied in practice. In particular, the Kalman filter is stable for estimating the state vector of linear dynamical systems that are stable or unstable, for arbitrarily slow measurement rates, provided that the mild technical assumptions are fulfilled. These assumptions require that the dimension of the state vector is minimal and that the measurement error covariance matrix and the process noise covariance matrices are positive

definite, although weaker conditions are also sufficient for stability in some cases; see Kailath et al. (2000) for such details on the stability of the Kalman filter. Kalman filter stability is connected with observability and controllability of the input-output model of the relevant dynamical system in Kalman (1963) The corresponding algorithm for continuous time linear measurements (with Gaussian additive white noise) and continuous time linear dynamical systems (with Gaussian additive white process noise) is called the Kalman-Bucy filter; see Kalman (1961).

Design Issues

In engineering practice, almost all real-world applications are nonlinear or non-Gaussian, and therefore, they do not fit the Kalman filter theory. Nevertheless, by approximating the nonlinear dynamics and measurements with linear equations, one can apply the Kalman filter theory; this is called the "extended Kalman filter" (EKF); see Gelb et al. (1974). The linearization of the nonlinear dynamics and measurements is made by computing the first-order Taylor series expansion and evaluating it at the estimated state vector; this is a very simple and fast approximation that is widely used in real- world applications, and it often gives good estimation accuracy, although there is no guarantee of that. Moreover, there is no guarantee that the EKF will be stable, even if the linearized system satisfies all the theoretical requirements for stability of the Kalman filter.

Even if the dynamics and measurements are exactly linear and if the measurement noise and process noise and initial uncertainty are all exactly Gaussian with exactly known means and covariance matrices, there can still be significant practical problems with Kalman filter accuracy, owing to ill-conditioning. In particular, the Kalman filter can be extremely sensitive to quantization errors in the computer arithmetic and storage. On the other hand, there are many different methods to try to mitigate ill-conditioning including (1) double or quadruple or octuple precision arithmetic, (2) making the covariance matrices symmetric before and after

every operation, (3) Tychonov regularization, (4) tuning the process noise covariance matrix, (5) coding the Kalman filter in principal coordinates or approximately principal coordinates (i.e., aligned with the eigenvectors of the state vector error covariance matrix), (6) sequential scalar measurement updates in a preferred order, and (7) various factorizations of the covariance matrices (e.g., square root, information matrix, information square root, upper triangular and lower triangular factorization, UDL, etc.). The classic book on error covariance matrix factorizations is by Bierman (2006). Unfortunately, there is no guarantee that the Kalman filter will work well even if all of these mitigation methods are used. Moreover, there is no useful theoretical analysis of this phenomenon, with the exception of a few not very tight upper bounds on the condition number. Plotting the numerical values of the condition number of the covariance matrix vs. time is often a helpful diagnostic. In certain real-world applications, the condition number of the Kalman filter error covariance matrix can be ten billion or larger.

Why Is the Kalman Filter So Useful and Popular?

The Kalman filter has been enormously successful in real-world applications, and it is interesting to reflect on why it has been so useful and so popular. In particular, Kalman himself believes that his filter was successful because it was based on probability rather than statistics; see Kalman (1978). For example, the error covariance matrix for the Kalman filter is computed from the assumed dynamics and measurement model and the assumed values of the initial state uncertainty and process noise and measurement noise covariance matrices, rather than by computing sample covariance matrices. Likewise, the Kalman filter computes the estimated state vector from assumed Gaussian and linear probability models, rather than computing the sample mean, as would be done in statistics. There is substantial wisdom in Kalman's assertion, owing to the difficulty of estimating sample covariance matrices

and sample vectors that are sufficiently accurate, given a limited number of samples and ill-conditioning and high-dimensional state vectors. A second reason that Kalman filters are so popular is that the real-time computational complexity is very reasonable for modern digital computers, even for problems with a high-dimensional state vector. In particular, the computational complexity of the Kalman filter scales as the cube of the dimension of the state vector; for example, the modern GPS system uses a Kalman filter with a state vector of dimension of about 1,000 to jointly estimate the orbits of the satellites in the GPS constellation. In 1960, when Kalman's paper was first published, digital computers were starting to become fast enough at reasonable cost to multiply large matrices in real time, which is the most challenging computation in a Kalman filter. Today computers are roughly ten orders of magnitude faster per unit cost than in 1960, and hence, we can run Kalman filters for high-dimensional problems on very inexpensive computers that fit into your wristwatch. A third reason that Kalman filters are popular is that the algorithms are easy to understand and code and test. A fourth reason is the guaranteed stability of the Kalman filter under very mild conditions which can always be satisfied in practical applications. A fifth reason is that the Kalman filter is optimal for time-varying unstable linear dynamics with time-varying measurement noise covariance and process noise covariance. A sixth reason is that one can use Kalman filters for nonlinear problems by approximating the nonlinear dynamics and measurement equations with a first-order Taylor series; this is called the extended Kalman filter (EKF), which is without a doubt the most widely used algorithm in real-world estimation applications. A seventh reason is that the Kalman filter automatically provides a convenient quantification of uncertainty of the estimated state vector using the error covariance matrix. The final reason is that it is easy to test the accuracy of the Kalman filter by comparing the theoretical error covariance matrix to errors computed by Monte Carlo simulations of the filter; the two errors should agree approximately, and statistically significant discrepancies suggest

bugs in the code or ill-conditioning of the error covariance matrices or nonlinearities or errors in modeling the dynamics or measurements.

Kalman's 1960 paper represented a big paradigm shift in two ways: (1) it exploited fast low-cost modern digital computers, whereas the literature up to that time did not, and (2) it used time domain methods rather than the ubiquitous Fourier transform methods, which limited the dynamics to steady state asymptotic in time, which in turn limited the theory to cover stable dynamics. Of course today we take both of these big points as normal engineering rather than revolutionary and surprising. The state of the art prior to Kalman's 1960 paper was the Wiener filter, which was based firmly on the Fourier transform. The Wiener filter required very lengthy and cumbersome algebraic spectral factorization with complex variables, resulting in erroneous formulas published in certain books, owing to algebraic errors which were not obvious and which could not be checked by computers, owing to the nonexistence of computer algebra software (e.g., MATHEMATICA) in 1960. Kalman explains many other problems with the Wiener filter in Kalman (2003).

Summary and Future Directions

To a large extent the Kalman filter theory is complete. There is a simple and useful theory of stability of the Kalman filter, which is completely lacking for nonlinear filters including the extended Kalman filter (EKF) and particle filters. Moreover, there are many robust versions of the Kalman filter that have been invented to mitigate ill-conditioning of the covariance matrix as well as uncertainty in system models and system parameters. However, there remain many important design issues that need to be addressed for practical applications; see Daum (2005) for details. The most obvious issues include nonlinear measurements, nonlinear plant models, robustness to uncertainty in measurement models and plant models, non-Gaussian measurement noise and plant noise, non-Gaussian initial uncertainty in the state vector, and ill-conditioning

of the error covariance matrix. That is, any deviation from the exact mathematical assumptions in the Kalman filter theory can cause problems in practice. It is the job of engineers to mitigate such problems and design filters that are robust to such perturbations. Kalman's recent papers on how the Kalman filter was invented and why it is so popular contain interesting and useful ideas; see Kalman (1978) and Kalman (2003).

KYP Lemma and Generalizations/Applications

Tetsuya Iwasaki
Department of Mechanical & Aerospace Engineering, University of California, Los Angeles, CA, USA

Abstract

Various properties of dynamical systems can be characterized in terms of inequality conditions on their frequency responses. The Kalman-Yakubovich-Popov (KYP) lemma shows equivalence of such frequency domain inequality (FDI) and a linear matrix inequality (LMI). The fundamental result has been a basis for robust and optimal control theories in the past several decades. The KYP lemma has recently been generalized to the case where an FDI on a possibly improper transfer function is required to hold in a (semi)finite frequency range. The generalized KYP lemma allows us to directly deal with practical situations where design parameters are sought to satisfy FDIs in multiple (semi)finite frequency ranges. Various design problems, including FIR filter and PID controller, reduce to LMI problems which can be solved via semidefinite programming.

Keywords

Bounded real; Frequency domain inequality; Linear matrix inequality; Multi-objective design; Optimal control; Positive real; Robust control

Introduction

In linear systems analysis and control design, dynamical properties are often characterized by frequency responses. The shape of a frequency response, as visualized by the Bode or Nyquist plot, is closely related to various performance measures including the

steady state error, fast and smooth transient, and robustness against unmodeled dynamics. Hence, desired system properties can be formalized in terms of a set of frequency domain inequalities (FDIs) on selected transfer functions. The analysis and design problems then reduce to verification and satisfaction of the FDIs.

The Kalman-Yakubovich-Popov (KYP) lemma (Anderson 1967; Kalman 1963; Rantzer 1996; Willems 1971) establishes the equivalence between an FDI and a linear matrix inequality (LMI). The LMI is defined by state space matrices of the transfer function in the FDI so that the FDI holds true if and only if the LMI admits a solution. The LMI characterization of an FDI is useful since it replaces the process of checking the FDI at infinitely many frequency points by the search for a symmetric matrix satisfying a finite dimensional convex constraint defined by the LMI. In addition to exact and tractable computations, benefits of the LMI conditions include analytical understanding of robust and optimal controls through spectral factorizations and storage/Lyapunov functions. The KYP lemma is a fundamental result in the systems and control field that has provided, in the past half century, a theoretical basis for developments of various tools for system analysis and design.

A drawback of the KYP lemma is its inability to characterize an FDI in a finite frequency range. Feedback control designs typically involve a set of specifications given in terms of multiple FDIs in various frequency ranges. However, the KYP lemma is not capable of treating such FDIs directly since it has to consider the entire frequency range. To address this deficiency, the KYP lemma has recently been generalized to characterize an FDI in a finite frequency range exactly (Iwasaki et al. 2000). Further generalizations (Iwasaki and Hara 2005) are available for FDIs within various frequency ranges for both continuous- and discrete-time, possibly improper, rational transfer functions. The generalized KYP lemma allows for direct multiobjective design of filters, controllers, and dynamical systems.

KYP Lemma

The KYP lemma may be motivated from various aspects, but let us explain it as an extension of a gain condition. Consider a stable linear system

$$\dot{x} = Ax + Bu, \quad G(s) := (sI - A)^{-1}B,$$

where $x(t) \in \mathbb{R}^n$ is the state, $u(t) \in \mathbb{R}^m$ is the input, and $G(s)$ is the transfer function from u to x. If u is a disturbance to the system and x represents the error from a desired operating point, we may be interested in how large the state variables can become for a given magnitude of the disturbance. The gain $\|G(j\omega)\|$ captures this property for the case of a sinusoidal disturbance at frequency ω, where $\|\cdot\|$ denotes the spectral norm ($=$ absolute value for a scalar). If $\|G(j\omega)\| < \gamma$ holds for all frequency ω with a small γ, then the system has a good disturbance attenuation property.

A version of the KYP lemma states that the FDI $\|G(j\omega)\| < \gamma$ with $\gamma = 1$ holds for all frequency ω if and only if there exists a symmetric matrix P satisfying the LMI:

$$\begin{bmatrix} PA + A^\mathsf{T}P + I & PB \\ B^\mathsf{T}P & -I \end{bmatrix} < 0.$$

Thus, existence of one particular P satisfying the LMI is enough to conclude that the gain is less than one for all, infinitely many, frequencies. This result is known as the bounded real lemma and has played a fundamental role in the robust and H_∞ control theories.

The KYP lemma can be introduced as a generalization of the bounded real lemma. First, note that the gain bound condition $\|G(j\omega)\| < 1$ and the LMI condition can equivalently be written as

$$\begin{bmatrix} G(j\omega) \\ I \end{bmatrix}^* \Theta \begin{bmatrix} G(j\omega) \\ I \end{bmatrix} < 0, \qquad (1)$$

$$\begin{bmatrix} PA + A^\mathsf{T}P & PB \\ B^\mathsf{T}P & 0 \end{bmatrix} + \Theta < 0, \qquad (2)$$

where

$$\Theta := \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix}.$$

In these equations, the particular matrix Θ is chosen to describe the gain bound condition as a special case of the quadratic form (1), and we observe that Θ appears in the LMI as in (2). It turns out that the equivalence of (1) and (2) holds not only for this particular Θ but also for an arbitrary symmetric matrix Θ. This result is called the KYP lemma, which states that, given arbitrary matrices A, B, and $\Theta = \Theta^\top$, the FDI (1) holds for all frequency ω if and only if there exists a matrix $P = P^\top$ satisfying the LMI (2), provided A has no eigenvalues on the imaginary axis.

The FDI in (1) can be specialized to an FDI

$$\begin{bmatrix} L(j\omega) \\ I \end{bmatrix}^* \Pi \begin{bmatrix} L(j\omega) \\ I \end{bmatrix} < 0. \qquad (3)$$

on transfer function

$$L(s) := C(sI - A)^{-1}B + D$$

by choosing

$$\Theta := \begin{bmatrix} C & D \\ 0 & I \end{bmatrix}^\top \Pi \begin{bmatrix} C & D \\ 0 & I \end{bmatrix}. \qquad (4)$$

The choice of matrix Π allows for characterizations of important system properties involving gain and phase of $L(s)$. For instance, the FDI (3) with

$$\Pi := \begin{bmatrix} 0 & -I \\ -I & 0 \end{bmatrix}$$

gives $L(j\omega) + L(j\omega)^* > 0$. This is called the positive real property, with which the phase angle remains between $\pm 90°$ when $L(j\omega)$ is a scalar.

Generalization

The standard KYP lemma deals with FDIs that are required to hold for all frequencies. To allow for more flexibility in practical system designs, the KYP lemma has been generalized to deal with FDIs in (semi)finite frequency ranges.

For instance, a version of the generalized KYP lemma states that the FDI (1) holds in the low frequency range $|\omega| \leq \varpi_\ell$ if and only if there exist matrices $P = P^\top$ and $Q = Q^\top > 0$ satisfying

$$\begin{bmatrix} A & B \\ I & 0 \end{bmatrix}^\top \begin{bmatrix} -Q & P \\ P & \varpi_\ell^2 Q \end{bmatrix} \begin{bmatrix} A & B \\ I & 0 \end{bmatrix} + \Theta < 0, \qquad (5)$$

provided A has no imaginary eigenvalues in the frequency range. In the limiting case where ϖ_ℓ approaches infinity and the FDI is required to hold for the entire frequency range, the solution Q to (5) approaches zero, and we recover (2).

The role of the additional parameter Q is to enforce the FDI only in the low frequency range. To see this, consider the case where the system is stable and a sinusoidal input $u = \Re[\hat{u}e^{j\omega t}]$, with (complex) phasor vector $\hat{u}$, is applied. The state converges to the sinusoid $x = \Re[\hat{x}e^{j\omega t}]$ in the steady state where $\hat{x} := G(j\omega)\hat{u}$. Multiplying (5) by the column vector obtained by stacking $\hat{x}$ and $\hat{u}$ in a column from the right, and by its complex conjugate transpose from the left, we obtain

$$(\varpi_\ell^2 - \omega^2)\hat{x}^* Q \hat{x} + \begin{bmatrix} \hat{x} \\ \hat{u} \end{bmatrix}^* \Theta \begin{bmatrix} \hat{x} \\ \hat{u} \end{bmatrix} < 0.$$

In the low frequency range $|\omega| \leq \varpi_\ell$, the first term is nonnegative, enforcing the second term to be negative, which is exactly the FDI in (1). If ω is outside of the range, however, the first term is negative, and the FDI is not required to hold.

Similar results hold for various frequency ranges. The term involving Q in (5) can be expressed as the Kronecker product $\Psi \otimes Q$ with Ψ being a diagonal matrix with entries $(-1, \varpi_\ell^2)$. The matrix Ψ arises from characterization of the low frequency range:

$$\begin{bmatrix} j\omega \\ 1 \end{bmatrix}^* \Psi \begin{bmatrix} j\omega \\ 1 \end{bmatrix} = \varpi_\ell^2 - \omega^2 \geq 0.$$

By different choices of Ψ, middle and high frequency ranges can also be characterized:

	Low	Middle	High
$\boldsymbol{\Omega}$	$\lvert\omega\rvert \leq \varpi_\ell$	$\varpi_1 \leq \omega \leq \varpi_2$	$\lvert\omega\rvert \geq \varpi_h$
Ψ	$\begin{bmatrix} -1 & 0 \\ 0 & \varpi_\ell^2 \end{bmatrix}$	$\begin{bmatrix} -1 & j\varpi_c \\ -j\varpi_c & -\varpi_1\varpi_2 \end{bmatrix}$	$\begin{bmatrix} 1 & 0 \\ 0 & -\varpi_h^2 \end{bmatrix}$

where $\varpi_c := (\varpi_1 + \varpi_2)/2$ and $\boldsymbol{\Omega}$ is the frequency range. For each pair $(\boldsymbol{\Omega}, \Psi)$, the FDI (1) holds in the frequency range $\omega \in \boldsymbol{\Omega}$ if and only if there exist real symmetric matrices P and $Q > 0$ satisfying

$$F^{\mathsf{T}}(\Phi \otimes P + \Psi \otimes Q)F + \Theta < 0, \quad (6)$$

provided A has no eigenvalues in $\boldsymbol{\Omega}$, where

$$\Phi := \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad F := \begin{bmatrix} A & B \\ I & 0 \end{bmatrix}.$$

Further generalizations are available Iwasaki and Hara (2005). The discrete-time case (frequency variable on the unit circle) can be similarly treated by a different choice of Φ. FDIs for descriptor systems and polynomial (rather than rational) functions can also be characterized in a form similar to (6) by modifying the matrix F. More specifically, the choices

$$\Phi := \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}, \quad F := \begin{bmatrix} A & B \\ E & O \end{bmatrix}$$

give the result for the discrete-time transfer function $L(z) = (zE - A)^{-1}(B - zO)$.

Applications

The generalized KYP lemma is useful for a variety of dynamical system designs. As an example, let us consider a classical feedback control design via shaping of a scalar open-loop transfer function in the frequency domain. The objective is to design a controller $K(s)$ for a given plant $P(s)$ such that the closed-loop system is stable and possesses a good performance dictated by reference tracking, disturbance attenuation, noise sensitivity, and robustness against uncertainties.
KYP Lemma and Generalizations/Applications, Fig. 1 Loop shaping design specifications

Typical design specifications are given in terms of bounds on the gain and phase of the open-loop transfer function $L(s) := P(s)K(s)$ in various frequency ranges as shown in Fig. 1. The controller $K(s)$ should be designed so that the frequency response $L(j\omega)$ avoids the shaded regions. For instance, the gain should satisfy $\lvert L(j\omega)\rvert \geq 1$ for $\lvert\omega\rvert < \omega_2$ and $\lvert L(j\omega)\rvert \leq 1$ for $\lvert\omega\rvert > \omega_3$ to ensure the gain crossover occurs in the range $\omega_2 \leq \omega \leq \omega_3$, and the phase bound $\angle L(j\omega) \geq \theta$ in this range ensures robust stability by the phase margin.

The design specifications can be expressed as FDIs of the form (3), where a particular gain or phase condition can be specified by setting Π as

$$\pm \begin{bmatrix} 1 & 0 \\ 0 & -\gamma^2 \end{bmatrix} \quad \text{or} \quad \begin{bmatrix} 0 & j - \tan\theta \\ -j - \tan\theta & 0 \end{bmatrix}$$

with $\gamma = \gamma_1$, γ_4, or 1, and the $+/-$ signs for upper/lower gain bounds. These FDIs in the corresponding frequency ranges can be converted to inequalities of the form (6) with Θ given by (4).

The control problem is now reduced to the search for design parameters satisfying the set of

inequality conditions (6). In general, both coefficient matrices F and Θ may depend on the design parameters, but if the poles of the controller are fixed (as in the PID control), then the design parameters will appear only in Θ. If in addition an FDI specifies a convex region for $L(j\omega)$ on the complex plane, then the corresponding inequality (6) gives a convex constraint on P, Q, and the design parameters. This is the case for specifications of gain upper bound (disk: $|L| < \gamma$) and phase bound (half plane: $\theta \leq \angle L \leq \theta + \pi$). A gain lower bound $|L| > \gamma$ is not convex but can often be approximated by a half plane. The design parameters satisfying the specifications can then be computed via convex programming.

Various design problems other than the open-loop shaping can also be solved in a similar manner, including finite impulse response (FIR) digital filter design with gain and phase constraints in a passband and stop-band and sensor or actuator placement for mechanical control systems (Hara et al. 2006; Iwasaki et al. 2003). Control design with the Youla parametrization also falls within the framework if a basis expansion is used for the Youla parameter and the coefficients are sought to satisfy convex constraints on closed-loop transfer functions.

Summary and Further Directions

The KYP lemma has played a fundamental role in systems and control theories, equivalently converting an FDI to an LMI. Dynamical systems properties characterized in the frequency domain are expressed in terms of state space matrices without involving the frequency variable. The resulting LMI condition has been found useful for developing robust and optimal control theories.

A recent generalization of the KYP lemma characterizes an FDI for a possibly improper rational function in a (semi)finite frequency range. The result allows for direct solutions of practical design problems to satisfy multiple specifications in various frequency ranges. A design problem is essentially solvable when transfer functions are affine in the design parameters and are required

to satisfy convex FDI constraints. An important problem, which falls outside of this framework and remains open, is the design of feedback controllers to satisfy multiple FDIs on closed-loop transfer functions in various frequency ranges. There have been some attempts to address this problem, but none of them has so far succeeded to give an exact solution.

The KYP lemma has been extended in other directions as well, including FDIs with frequency-dependent weights (Graham and de Oliveira 2010), internally positive systems (Tanaka and Langbort 2011), full rank polynomials (Ebihara et al. 2008), real multipliers (Pipeleers and Vandenberghe 2011), a more general class of FDIs (Gusev 2009), multidimensional systems (Bachelier et al. 2008), negative imaginary systems (Xiong et al. 2012), symmetric formulations for robust stability analysis (Tanaka and Langbort 2013), and multiple frequency intervals (Pipeleers et al. 2013). Extensions of the KYP lemma and related S-procedures are thoroughly reviewed in Gusev and Likhtarnikov (2006). A comprehensive tutorial of robust LMI relaxations is provided in Scherer (2006) where variations of the KYP lemma, including the generalized KYP lemma as a special case, are discussed in detail.

Mechatronics Group, Chalmers University of
Technology, Göteborg, Sweden

Abstract

This chapter provides an overview of lane keeping systems. First, a general architecture is introduced and existing solutions for the necessary sensors and actuators are then overviewed. The threat assessment and the lane position control problems are discussed, highlighting challenges and solutions implemented in lane keeping systems available on the market.

Keywords

Active safety; Decision-making and control; Intelligent transportation systems; Threat assessment

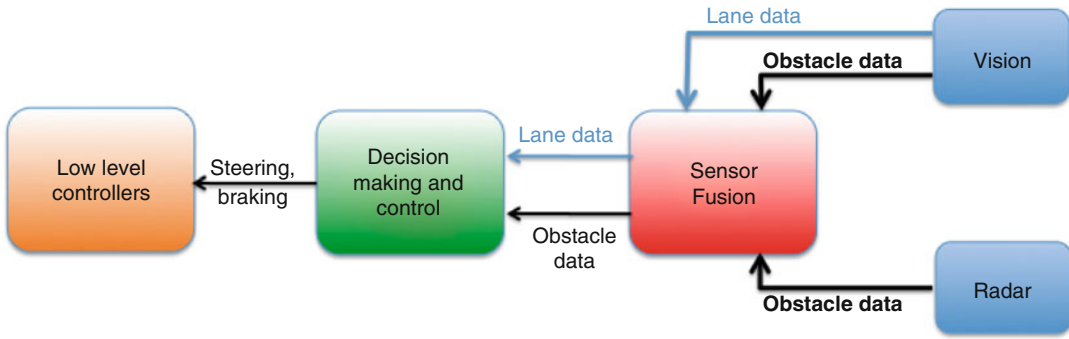
Introduction

Lane keeping systems are vehicle guidance systems that aim at preventing lane departure maneuvers, which may lead to accidents, i.e., collision with surrounding obstacles and vehicles.

By resorting to radar and/or lasers and cameras, a lane keeping system monitors the adjacent lanes. Crossing the lane markings in the absence of vehicles and/or obstacles in the adjacent lanes should not cause any reaction of the lane keeping systems and let the driver freely perform the lane change maneuver. In the presence of vehicles or obstacles in the adjacent lanes, the system should assess the threat and, in case a risk of collision is detected, either warn the driver or automatically issue either a steering or a single-wheel braking command, in order to prevent the crossing of the lane markings. As discussed next, despite the simplicity of the threat assessment and the decision-making and control problem, challenges arise in real traffic scenarios which may lead to nuisance due to unnecessary warnings and/or assisting interventions.

In this entry, we overview the most important aspects in the design of a lane keeping system. This entry is structured as follows. Section "Lane Keeping Systems Architecture" illustrates a generic architecture. Section "Sensing and Actuation" reviews the most used sensors suitable for lane keeping applications. Section "Decision Making and Control" introduces the threat assessment and the lane position control problems, highlighting the most relevant challenges.

Lane Keeping Systems Architecture

The main components of a lane keeping system and their interconnections are shown in Fig. 1.


Lane Keeping, Fig. 1 The lane keeping architecture

Relative positions and velocities of the host vehicle w.r.t. the surrounding environment are measured by one radar, typically installed on the front of the vehicle, and possibly by the camera, typically installed on the windshield. Position of the host vehicle within the lane and further information, e.g., road geometry, are measured by the camera. These measurements are then fused by the *sensor fusion* module to provide accurate measurements of the position and velocity of the vehicle w.r.t. the surrounding environment and the lane in the widest range of operating conditions and scenarios.

The task of the *decision-making and control module* is to assess the risk that the vehicle crosses the lane in a dangerous way and, possibly, to take an action that can range from warning the driver or issuing an assisting intervention, e.g., braking and/or steering. Such steering and braking commands are actually implemented by *low-level controllers*.

The different modules will be overviewed in the following sections.

Sensing and Actuation

Radar
Radars for automotive applications are placed in the front of the car, typically behind the grille. The radar emits radio waves and distance from the vehicle ahead is calculated by measuring the arrival time and direction of the reflected radio waves. The relative velocity is determined by relying on the Doppler effect, i.e., by measuring the frequency change of the reflected waves. Relative distance and velocity measurements are typically updated with a frequency of 10 Hz.

Radars for automotive applications emit waves with a frequency of 77 GHz and detect objects within an approximate range of 150 m and a view angle of about $\pm 10°$, with a deviation of 20–30 cm from the correct value for 95 % of the measurements (Eidehall 2004). New radar systems increase the range up to about 200 m with a view angle of about $\pm 10°$ (News Releases DENSO Corporation 2013a).

Typically, radar units are equipped with computer systems running signal processing algorithms that detect and track objects and, for each of them, calculate relative position and speed, azimuth angle, also providing additional information, e.g., the time an object has been tracked and a flag indicating that a target has been locked. Such additional information are typically used in logics implementing the decision-making algorithms of, among others, the lane keeping system.

There are several issues arising from the use of a radar in automotive applications, e.g., wave reflections due to road bumps and barriers that may induce the signal processing algorithms to false object detections (Eidehall 2004). Moreover, interference and the vehicle dynamics (News Releases DENSO Corporation 2013a), e.g., pitching due to braking, may limit the capability of the signal processing algorithms of correctly detecting and tracking the surrounding objects. The latter may be solved by, e.g., using electric motors that

adjust the radar antenna axes in order to compensate for the vehicle dynamics (News Releases DENSO Corporation 2013a).

Vision Systems

Vision systems in lane keeping applications are typically based on a single, CCD camera mounted next to the rear-view mirror placed at the center of the windshield. The image is typically captured by 640×480 pixels and then processed by an image processing unit. The sampling time of the vision system is about 0.1 s, but it can change depending on, e.g., the complexity of the scene, for example, in city traffic (Eidehall 2004).

Lane markings are detected by using differences in the image contrast (Technology Daimler and Safety Innovation 2013). The camera can be either monochrome or full colored. The latter is used to enhance the detection of lane markings, which have different colors around the world (News Releases DENSO Corporation 2013b). Distances to the lane markings and road geometry parameters, like heading angle and curvature, are determined by the image processing algorithms, which must be robust to poor image due to bad weather conditions or worn lane markings. Estimation of road geometry parameters, like curvature measurement, can be a challenging problem (Lundquist and Schön 2011), especially during rain or fog (Eidehall 2004).

Depending on the image processing algorithms the cameras are equipped with, surrounding objects can also be detected and tracked. In particular, pattern recognition algorithm can be used to find objects in the images and classify them into cars, trucks, motorcycles, and pedestrians. Vehicles (or other objects) can be typically detected in a range of about 60–70 m, with lower accuracy than a radar (Eidehall 2004).

Actuators

In order to keep the vehicle within its lane, the most convenient actuator is the steering. Hence, a lane keeping system can be quite easily built in those vehicles equipped with electric power-assisted steering (EPAS) systems. In particular, an additional steering torque can be added by the EPAS to the driver's steering torque, in order to generate the desired yaw moment calculated by the *decision-making and control module*.

Clearly, the steering command is not the only available to affect the vehicle yaw motion, thus changing its orientation and lateral position within the lane. Individual wheel braking may also be used (Technology Daimler and Safety Innovation 2013). In particular, in vehicles equipped with yaw motion control system via individual braking, a braking torque request for each wheel can be sent to the yaw motion control system in order to generate the desired yaw motion.

Decision Making and Control

The decision making and control in a lane keeping problem can be conceptually divided into two tasks: *the threat assessment* and *the lane position control*. The threat assessment problem can be stated as the problem of detecting the risk of accident due to an unintended lane departure, for a given situation of the surrounding environment (i.e., surrounding vehicles and obstacles). The lane position control problem is the problem of controlling the vehicle yaw and lateral motion in order to stay within the lane. The lane position control is activated once the threat assessment detects the risk of accident.

We point out that the border between the corresponding modules executing these two tasks may be blurred for different existing commercial lane keeping systems. That is, the two problems may not be solved by two separate modules, but rather seen and solved as a single problem. Moreover, the following presentation of the threat assessment and the lane position control problems and approaches abstracts from the implementation of a particular lane keeping system available on the market, rather focusing on fundamental concepts.

Threat Assessment

The core information in a threat assessment algorithm for lane keeping applications is given by a measure called time to lane crossing (TLC). This is the predicted time when a front tire intersects a

lane boundary. As explained in van Winsum et al. (2000), the TLC can be calculated in different ways. Next, its simplest expression is reported as (Eidehall 2004)

$$\text{TLC} = \frac{W/2 - W_{\text{veh}}/2 - y_{\text{off}}}{\dot{y}_{\text{off}}}, \qquad (1)$$

where W is the lane width, y_{off} is the vehicle lateral position within the lane, and W_{veh} is the vehicle width. Equation (1) can be easily modified to calculate the TLC w.r.t. any lane boundary relative to the adjacent lanes.

The simplest way of using the TLC is just monitoring it and triggering an action as the TLC passes a threshold. Nevertheless, depending on the vehicle manufacturer, more sophisticated logics can be developed in order to correctly interpret the driver's intention and minimize the unnecessary assisting interventions. Next, few scenarios follow that must be taken into account while developing such logics in order to not interfere with the driver. In particular, the threat assessment module should stop or not trigger any assisting intervention while the vehicle is approaching or crossing a lane boundary if

- The indicators are active,
- A risk of collision with the vehicle ahead is detected, such that the vehicle is crossing the lane markings as results of an evasive maneuver,
- The radar detects a slower vehicle ahead and the driver accelerates, since this may be an overtaking (Technology Daimler and Safety Innovation 2013),
- The driver's steering wheel torque indicates that the driver is acting against the system,
- The driver manually initiates a maneuver, driving the vehicle back to its lane (i.e., the driver executes "the right" maneuver)
- The vehicle enters a motor highway or a bend (Technology Daimler and Safety Innovation 2013).

Part of the threat assessment task is predicting the trajectories of the surrounding vehicles. For instance, if a *threat* vehicle is traveling in the adjacent lane (in the same or opposite direction), its position has to be predicted at the TLC in order to decide whether to trigger an intervention, if a collision is predicted, or not (Eidehall 2004). This step is repeated for all the detected threat vehicles, provided that the onboard radar and the camera support multiple-target tracking.

In order to minimize the interference of the lane keeping system with the driver and/or to not let the system perform dangerous maneuvers, assisting interventions should not be triggered if the quality of the measurements is such that the information about the surrounding environment is poor. For instance, in case of low visibility that limits the detection of the lane markings and the estimation of the road geometry, the system should be temporarily deactivated or downgraded.

In summary, the threat assessment module has to be designed with the objective of detecting the risk of accident due to lane departure while not interfering with the driver with unnecessary interventions (i.e., nuisance minimization).

Lane Position Control

As observed in section "Actuators," the vehicle motion within the lane can be affected in two ways, i.e., through steering and individual wheel braking. Clearly, a steering command can be issued by both the driver and the lane keeping system.

Before issuing a steering command, in order to minimize the system nuisance, the lane keeping system may issue other types of low-intrusiveness interventions. For instance, if a "low"-level threat is detected by the threat assessment module (i.e., a threat where the risk of accidents is not imminent), warnings or other stimuli to the driver may be issued in order to induce the driver to execute the right maneuver. For instance, based on, e.g., spectrum analysis of the driver's steering command, driver's inattention or drowsiness may be detected and a warning issued. As observed in Technology Daimler and Safety Innovation (2013), different types of warning can be used for different vehicle types. In passenger cars, in such cases, a vibration motor in the steering wheel may warn the driver. In trucks, audible, directional warning signals can be used to let the driver know
Lane Keeping, Fig. 2 Vehicle modeling notation

that the vehicle trajectory needs to be adjusted. In buses, in order to avoid bothering the passengers, driver warning is issued through vibration motors placed in the driver's seat.

Other types of "soft intervention" aim at increasing the steering impedance in the direction leading to lane crossing that might cause a collision with surrounding vehicles. Generating the desired steering impedance can be easily formulated as a steering torque control problem. Nevertheless, tuning the control algorithm to obtain the desired steering feeling can be an involving and time-consuming procedure based on extensive in-vehicle testing.

Besides warnings and "soft interventions" aiming at inducing the driver to perform correct maneuvers, as part of the lane position control

task in a lane keeping system, a lateral control algorithm w.r.t. the lane boundaries is needed. Consider the vehicle sketched in Fig. 2. The equations describing the vehicle motion within the lane can be compactly written in a state-space form as

$$\dot{x} = Ax + B\delta + D\dot{\psi}_{\text{des}}, \qquad (2)$$

where $x = \begin{bmatrix} e_y & \dot{e}_y & e_\psi & \dot{e}_\psi \end{bmatrix}$, $\dot{\psi}_d$ is the desired yaw rate, e.g., calculated based on the road curvature, and A, B, D are speed-dependent matrices that can be found in Rajamani (2003). The (unstable) system can be stabilized by a state-feedback control law

$$\delta = -Kx + \delta_{ff}, \qquad (3)$$

where K is a stabilizing static gain and δ_{ff} is a feedforward term that can be used to compensate for the road curvature. In Rajamani (2003), it is shown that, while $e_y(t) \to 0$ as $t \to 0$, e_ψ approaches a nonzero steady-state value, no matter how δ_{ff} is chosen, for non-straight road.

Despite a simple problem formulation and solution, controlling the vehicle position within the lane is not a trivial task. Indeed, having the control law (3) active all the time may increase the nuisance, leading to unacceptable driving experience. For this reason, the steering command calculated through the (3) may be active only when the vehicle significantly deviates from the road centerline, i.e., approaches the lane markings. Clearly, adding such logics complicates the analysis of the closed-loop behavior, thus making necessary extensive in-vehicle tuning and verification.

Summary and Future Directions

In this chapter, we have overviewed the general issues and requirements that must be considered in the design of a lane-keeping system.

The variety of environmental conditions the sensing system should operate in, together with the range of diverse scenarios the decision-making module should cope with, render the design and verification problems challenging, costly, and time consuming for a lane-keeping system. It is, therefore, necessary to approach the design of such systems by also providing safety guarantees to the largest extent, yet minimizing conservatism and intrusiveness of the overall system. Model-based approaches to threat assessment and decision-making problems, as proposed in Falcone et al. (2011) for a lane departure application, provide neat design and verification frameworks, which can clearly describe the safe operation of the overall system. Adopting such design methodologies can potentially contribute to a consistent reduction of the development time by consistently reducing the a posteriori safety verification phase. On the other hand, the computational complexity of formal model-based verification methods can dramatically increase in those scenarios where system nonlinearity and nonconvex state spaces become relevant. Hence, future research efforts aiming at developing low-complexity verification methods might greatly impact the future development of automated driving systems.

Learning in Games

Jeff S. Shamma
School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, GA, USA

Abstract

In a Nash equilibrium, each player selects a strategy that is optimal with respect to the strategies of other players. This definition does not mention the process by which players reach a

Nash equilibrium. The topic of learning in games seeks to address this issue in that it explores how simplistic learning/adaptation rules can lead to Nash equilibrium. This entry presents a selective sampling of learning rules and their long-run convergence properties, i.e., conditions under which player strategies converge or not to Nash equilibrium.

Keywords

Cournot best response; Fictitious play; Log-linear learning; Mixed strategies; Nash equilibrium

Introduction

In a *Nash equilibrium*, each player's strategy is optimal with respect to the strategies of other players. Accordingly, Nash equilibrium offers a predictive model of the outcome of a game. That is, given the basic elements of a game – (i) a set of players; (ii) for each player, a set of strategies; and (iii) for each player, a utility function that captures preferences over strategies – one can model/assert that the strategies selected by the players constitute a Nash equilibrium.

In making this assertion, there is no suggestion of *how* players may come to reach a Nash equilibrium. Two motivating quotations in this regard are:

> The attainment of equilibrium requires a disequilibrium process (Arrow 1986).

and

> The explanatory significance of the equilibrium concept depends on the underlying dynamics (Skyrms 1992).

These quotations reflect that a foundation for Nash equilibrium as a predictive model is dynamics that lead to equilibrium. Motivated by these considerations, the topic of "learning in games" shifts the attention away from equilibrium and towards underlying dynamic processes and their long-run behavior. The intent is to understand how players may reach an equilibrium as well

as understand possible barriers to reaching Nash equilibrium.

In the setup of learning in games, players repetitively play a game over a sequence of stages. At each stage, players use past experiences/observations to select a strategy for the current stage. Once player strategies are selected, the game is played, information is updated, and the process is repeated. The question is then to understand the long-run behavior, e.g., whether or not player strategies converge to Nash equilibrium.

Traditionally the dynamic processes considered under learning in games have players selecting strategies based on a myopic desire to optimize for the current stage. That is, players do not consider long-run effects in updating their strategies. Accordingly, while players are engaged in repetitive play, the dynamic processes generally are not optimal in the long run (as in the setting of "repeated games"). Indeed, the survey article of Hart (2005) refers to the dynamic processes of learning in games as "adaptive heuristics." This distinction is important in that an implicit concern in learning in games is to understand how "low rationality" (i.e., suboptimal and heuristic) processes can lead to the "high rationality" (i.e., mutually optimal) notion of Nash equilibrium.

This entry presents a sampling of results from the learning in games literature through a selection of illustrative dynamic processes, a review of their long-run behaviors relevant to Nash equilibrium, and pointers to further work.

Illustration: Commuting Game

We begin with a description of learning in games in the specific setting of the commuting game, which is a special case of so-called congestion games (cf., Roughgarden 2005). The setup is as follows. Each player seeks to plan a path from an origin to a destination. The origins and destinations can differ from player to player. Players seek to minimize their own travel times. These travel times depend both on the chosen path (distance traveled) *and* the paths of other players (road congestion). Every day, a player uses past

information and observations to select that day's path according to some selection rule, and this process is repeated day after day.

In game-theoretic terms, player "strategies" are paths linking their origins to destinations, and player "utility functions" reflect travel times. At a Nash equilibrium, players have selected paths such that no individual player can find a shorter travel time given the chosen paths of others. The learning in games question is then whether player paths indeed converge to Nash equilibrium in the long run. Not surprisingly, the answer depends on the specific process that players use to select paths and possible additional structure of the commuting game.

Suppose that one of the players, say "Alice," is choosing among a collection of paths. For the sake of illustration, let us give Alice the following capabilities: (i) Alice can observe the paths chosen by all other players and (ii) Alice can compute off-line her travel time as a function of her path and the paths of others.

With these capabilities, Alice can compute running averages of the travel times along all available paths. Note that the assumed capabilities allow Alice to compute the travel time of a path and hence its running average, *whether or not* she took the path on that day. With average travel time values in hand, two possible learning rules are:

– *Exploitation:* Choose the path with the lowest average travel time.
– *Exploitation with Exploration:* With high probability, choose the path with the lowest average travel time, and with low probability, choose a path at random.

Assuming that all players implement the same learning rule, each case induces a dynamic process that governs the daily selection of paths and determines the resulting long-run behavior. We will revisit these processes in a more formal setting in the next section.

A noteworthy feature of these learning rules is that they do not explicitly depend on the utility functions of other players. For example, suppose one of the other players is willing to trade off travel time for more scenic routes. Similarly, suppose one of the other players prefers to travel

on high congestion paths, e.g., a rolling billboard seeking to maximize exposure. The aforementioned learning rules for Alice remain unchanged. Of course, Alice's actions implicitly depend on the utility functions of other players, but only indirectly through their selected paths. This characteristic of no explicit dependence on the utility functions of others is known as "uncoupled" learning, and it can have major implications on the achievable long-run behavior (Hart and Mas-Colell 2003a).

In assuming the ability to observe the paths of other players and to compute off-line travel times as a function of these paths, these learning rules impose severe requirements on the information available to each player. Less restrictive are learning rules that are "payoff based" (Young 2005). A simple modification that leads to payoff-based learning is as follows. Alice maintains an empirical average of the travel times of a path using only the days that she took that path. Note the distinction – on any given day, Alice remains unaware of travel times for the routes not selected. Using these empirical average travel times, Alice can then mimic any of the aforementioned learning rules. As intended, she does not directly observe the paths of others, nor does she have a closed-form expression for travel times as a function of player paths. Rather, she only can select a path and measure the consequences. As before, all players implementing such a learning rule induce a dynamic process, but the ensuing analysis in payoff-based learning can be more subtle.

Learning Dynamics

We now give a more formal presentation of selected learning rules and results concerning their long-run behavior.

Preliminaries

We begin with the basic setup of games with a finite set of players, $\{1, 2, \ldots, N\}$, and for each player i, a finite set of strategies, $\mathcal{A}_i$. Let

$$\mathcal{A} = \mathcal{A}_1 \times \ldots \times \mathcal{A}_N$$

denote the set of strategy profiles. Each player, i, is endowed with a utility function

$$u_i : \mathcal{A} \to \mathbb{R}.$$

Utility functions capture player preferences over strategy profiles. Accordingly, for any $a, a' \in \mathcal{A}$, the condition

$$u_i(a) > u_i(a')$$

indicates that player i prefers the strategy profile a over a'.

The notation $-i$ indicates the set of players *other than* player i. Accordingly, we sometimes write $a \in \mathcal{A}$ as (a_i, a_{-i}) to isolate a_i, the strategy of player i, versus a_{-i}, the strategies of other players. The notation $-i$ is used in other settings as well.

Utility functions induce best-response sets. For $a_{-i} \in \mathcal{A}_{-i}$, define

$$\mathcal{B}_i(a_{-i}) = \{ a_i : u_i(a_i, a_{-i}) \ge u_i(a'_i, a_{-i})$$
$$\text{for all } a'_i \in \mathcal{A}_i \}.$$

In words, $\mathcal{B}_i(a_{-i})$ denotes the set of strategies that are optimal for player i in response to the strategies of other players, a_{-i}.

A strategy profile $a^* \in \mathcal{A}$ is a *Nash equilibrium* if for any player i and any $a'_i \in \mathcal{A}_i$,

$$u_i(a^*_i, a^*_{-i}) \ge u_i(a'_i, a^*_{-i}).$$

In words, at a Nash equilibrium, no player can achieve greater utility by unilaterally changing strategies. Stated in terms of best-response sets, a strategy profile, a^*, is a Nash equilibrium if for every player i,

$$a^*_i \in \mathcal{B}_i(a^*_{-i}).$$

We also will need the notions of *mixed strategies* and mixed strategy Nash equilibrium. Let $\Delta(\mathcal{A}_i)$ denote probability distributions (i.e., nonnegative vectors that sum to one) over the set $\mathcal{A}_i$. A mixed strategy profile is a collection of probability distributions, $\alpha = (\alpha_1, \ldots, \alpha_N)$, with

$\alpha_i \in \Delta(\mathcal{A}_i)$ for each i. Let us assume that players choose a strategy randomly and independently according to these mixed strategies. Accordingly, define $\mathbf{Pr}[a; \alpha]$ to be the probability of strategy a under the mixed strategy profile α, and define the expected utility of player i as

$$U_i(\alpha) = \sum_{a \in \mathcal{A}} u_i(a) \cdot \mathbf{Pr}[a; \alpha].$$

A *mixed strategy Nash equilibrium* is a mixed strategy profile, α^*, such that for any player i and any $\alpha'_i \in \Delta(\mathcal{A})$,

$$U_i(\alpha^*_i, \alpha^*_{-i}) \ge U_i(\alpha'_i, \alpha^*_{-i}).$$

Special Classes of Games

We will reference three special classes of games: (i) zero-sum games, (ii) potential games, and (iii) weakly acyclic games.

Zero-sum games: There are only two players (i.e., $N = 2$), and $u_1(a) = -u_2(a)$.

Potential games: There exists a (potential) function,

$$\phi : \mathcal{A} \to \mathbb{R}$$

such that for any pair of strategies, $a = (a_i, a_{-i})$ and $a' = (a'_i, a_{-i})$, that differ only in the strategy of player i,

$$u_i(a_i, a_{-i}) - u_i(a'_i, a_{-i}) = \phi(a_i, a_{-i}) - \phi(a'_i, a_{-i}).$$

Weakly acyclic games: There exists a function

$$\phi : \mathcal{A} \to \mathbb{R}$$

with the following property: if $a \in \mathcal{A}$ is *not* a Nash equilibrium, then at least one player, say player i, has an alternative strategy, say $a'_i \in \mathcal{A}_i$, such that

$$u_i(a'_i, a_{-i}) > u_i(a_i, a_{-i})$$

and

$$\phi(a'_i, a_{-i}) > \phi(a_i, a_{-i}).$$

Potential games are a special class of games for which various learning dynamics converge to

a Nash equilibrium. The aforementioned commuting game constitutes a potential game under certain special assumptions. These are as follows: (i) the delay on a road only depends on the number of users (and not their identities) and (ii) all players measure delay in the same manner (Monderer and Shapley 1996).

Weakly acyclic games are a generalization of potential games. In potential games, there exists a potential function that captures differences in utility under unilateral (i.e., single player) changes in strategy. In weakly acyclic games (see Young 1998), if a strategy profile is not a Nash equilibrium, then there *exists* a player who can simultaneously achieve an increase in utility while increasing the potential function. The characterization of weakly acyclic games through a potential function herein is not traditional and is borrowed from Marden et al. (2009a).

Forecasted Best-Response Dynamics

One family of learning dynamics involves players formulating a forecast of the strategies of other players based on past observations and then playing a best response to this forecast.

Cournot Best-Response Dynamics

The simplest illustration is Cournot best-response dynamics. Players repetitively play the same game over stages $t = 0, 1, 2, \ldots$. At stage t, a player forecasts that the strategies of other players are the strategies played at the previous stage $t - 1$. The following rules specify Cournot best response with inertia. For each stage t and for each player i:

- With probability $p \in (0, 1)$, $a_i(t) = a_i(t - 1)$ (inertia).
- With probability $1 - p$, $a_i(t) \in \mathcal{B}_i(a_{-i}(t-1))$ (best response).
- If $a_i(t - 1) \in \mathcal{B}_i(a_{-i}(t - 1))$, then $a_i(t) = a_i(t - 1)$ (continuation).

Proposition 1 *For weakly acyclic (and hence potential) games, player strategies under Cournot best-response dynamics with inertia converge to a Nash equilibrium.*

Cournot best-response dynamics need not always converge in games with a Nash equilibrium, hence the restriction to weakly acyclic games.

Fictitious Play

In fictitious play, introduced in Brown (1951), players also use past observations to construct a forecast of the strategies of other players. Unlike Cournot best-response dynamics, this forecast is *probabilistic*.

As a simple example, consider the commuting game with two players, Alice and Bob, who both must choose between two paths, A and B. Now suppose that on stage $t = 10$, Alice has observed Bob used path A for 6 out of the previous 10 days and path B for the remaining days. Then Alice's forecast of Bob is that he will chose path A with 60 % probability and path B with 40 % probability. Alice then chooses between path A and B in order to optimize her *expected* utility. Likewise, Bob uses Alice's empirical averages to form a probabilistic forecast of her next choice and selects a path to optimize his expected utility.

More generally, let $\pi_j(t) \in \Delta(\mathcal{A}_j)$ denote the *empirical frequency* for player j at stage t. This vector is a probability distribution that indicates the relative frequency of times player j played each strategy in $\mathcal{A}_j$ over stages $0, 1, \ldots, t - 1$. In fictitious play, player i assumes (incorrectly) that at stage t, other players will select their strategies independently and randomly according to their empirical frequency vectors. Let $\Pi_{-i}(t)$ denote the induced probability distribution over $\mathcal{A}_{-i}$ at stage t. Under fictitious play, player i selects an action according to

$$a_i(t) \in \arg \max_{a_i \in \mathcal{A}_i} \sum_{a_{-i} \in \mathcal{A}_{-i}} u_i(a_i, a_{-i})$$

$$\cdot \mathbf{Pr}[a_{-i}; \Pi_{-i}(t)].$$

In words, player i selects the action that maximizes expected utility assuming that other players select their strategies randomly and independently according to their empirical frequencies.

Proposition 2 *For (i) zero-sum games, (ii) potential games, and (iii) two-player games*

in which one player has only two actions, player empirical frequencies under fictitious play converge to a mixed strategy Nash equilibrium.

These results are reported in Fudenberg and Levine (1998), Hofbauer and Sandholm (2002), and Berger (2005). Fictitious play need not converge to Nash equilibria in all games. An early counterexample is reported in Shapley (1964), which constructs a two-player game with a unique mixed strategy Nash equilibrium. A weakly acyclic game with multiple pure (i.e., non-mixed) Nash equilibria under which fictitious play does not converge is reported in Foster and Young (1998).

A variant of fictitious play is "joint strategy" fictitious play (Marden et al. 2009b). In this framework, players construct as forecasts empirical frequencies of the *joint* play of other players. This formulation is in contrast to constructing and combining empirical frequencies for each player. In the commuting game, it turns out that joint strategy fictitious play is equivalent to the aforementioned "exploitation" rule of selecting the path with lowest average travel time. Marden et al. (2009b) show that action profiles under joint strategy fictitious play (with inertia) converge to a Nash equilibrium in potential games.

Log-Linear Learning

Under forecasted best-response dynamics, players chose a best response to the forecasted strategies of other players. Log-linear learning, introduced in Blume (1993), allows the possibility of "exploration," in which players can select nonoptimal strategies but with relatively low probabilities.

Log-linear learning proceeds as follows. First, introduce a "temperature" parameter, $T > 0$.

– At stage t, a single player, say player i, is selected at random.
– For player i,

$$\mathbf{Pr}[a_i(t) = a_i'] = \frac{1}{Z} e^{u_i(a_i', a_{-i}(t-1))/T}.$$

– For all other players, $j \neq i$,

$$a_j(t) = a_j(t - 1).$$

In words, under log-linear learning, only a single player performs a strategy update at each stage. The probability of selecting a strategy is exponentially proportional to the utility garnered from that strategy (with other players repeating their previous strategies). In the above description, the dummy parameter Z is a normalizing variable used to define a probability distribution. In fact, the specific probability distribution for strategy selection is a Gibbs distribution with temperature parameter, T. For very large T, strategies are chosen approximately uniformly at random. However, for small T, the selected strategy is a best response (i.e., $a_i(t) \in \mathcal{B}_i(a_{-i}(t-1))$) with high probability, and an alternative strategy is selected with low probability.

Because of the inherent randomness, strategy profiles under log-linear learning never converge. Nonetheless, the long-run behavior can be characterized probabilistically as follows.

Proposition 3 *For potential games with potential function $\phi(\cdot)$ under log-linear learning, for any $a \in \mathcal{A}$,*

$$\lim_{t \to \infty} \mathbf{Pr}[a(t) = a] = \frac{1}{Z} e^{\phi(a)/T}.$$

In words, the long-run probabilities of strategy profiles conform to a Gibbs distribution constructed from the underlying potential function. This characterization has the important implication of (probabilistic) equilibrium *selection*. Prior convergence results stated convergence to Nash equilibria, but did not specify which Nash equilibrium in the case of multiple equilibria. Under log-linear learning, there is a probabilistic preference for the Nash equilibrium that maximizes the underlying potential function.

Extensions and Variations

Payoff-based learning. The discussion herein presumed that players can observe the actions of other players and can compute utility functions off-line. Payoff-based algorithms, i.e., algorithms in which players only measure the utility

garnered in each stage, impose less restrictive informational requirements. See Young (2005) for a general discussion, as well as Marden et al. (2009c), Marden and Shamma (2012), and Arslan and Shamma (2004) for various payoff-based extensions.

No-regret learning. The broad class of so-called "no-regret" learning rules has the desirable property of converging to broader solution concepts (namely, Hannan consistency sets and correlated equilibria) in general games. See Hart and Mas-Colell (2000, 2001, 2003b) for an extensive discussion.

Calibrated forecasts. Calibrated forecasts are more sophisticated than empirical frequencies in that they satisfy certain long-run consistency properties. Accordingly, forecasted best-response learning using calibrated forecasts has stronger guaranteed convergence properties, such as convergence to correlated equilibria. See Foster and Vohra (1997), Kakade and Foster (2008), and Mannor et al. (2007).

Impossibility results. This entry focused on convergence results in various special cases. There are broad impossibility results that imply the impossibility of families of learning rules to converge to Nash equilibria in all games. The focus is on *uncoupled* learning, i.e., the learning dynamics for player i does not depend explicitly on the utility functions of other players (which is satisfied by all of the learning dynamics presented herein). See Hart and Mas-Colell (2003a, 2006), Hart and Mansour (2007), and Shamma and Arslan (2005). Another type of impossibility result concerns lower bounds on the required rate of convergence to equilibrium (e.g., Hart and Mansour 2010).

Welfare maximization. Of special interest is learning dynamics that select welfare (i.e., sum of utilities) maximizing strategy profiles, whether or not they are Nash equilibria. Recent contributions include Pradelski and Young (2012), Marden et al. (2011), and Arieli and Babichenko (2012).

Summary and Future Directions

We have presented a selection of learning dynamics and their long-run characteristics, specifically in terms of convergence to Nash equilibria. As stated early on, the original motivation of learning in games research has been to add credence to solution concepts such as Nash equilibrium as a model of the outcome of a game. An emerging line of research stems from engineering considerations, in which the objective is to use the framework of learning in games as a design tool for distributed decision architecture settings such as autonomous vehicle teams, communication networks, or smart grid energy systems. A related emerging direction is social influence, in which the objective is to steer the collective behaviors of human decision makers towards a socially desirable situation through the dispersement of incentives. Accordingly, learning in games can offer baseline models on how individuals update their behaviors to guide and inform social influence policies.

Introduction

How does a machine learn an abstract concept from examples? How can a machine generalize to previously unseen situations? Learning theory is the study of (formalized versions of) such questions. There are many possible ways to formulate such questions. Therefore, the focus of this entry is on one particular formalism, known as PAC (probably approximately correct) learning. It turns out that PAC learning theory is rich enough to capture intuitive notions of what learning should mean in the context of applications and, at the same time, is amenable to formal mathematical analysis. There are several precise and complete studies of PAC learning theory, many of which are cited in the bibliography. Therefore, this article is devoted to sketching some high-level ideas.

Keywords

Machine learning; Probably approximately correct (PAC) learning; Support vector machine; Vapnik-Chervonenkis (V-C) dimension

Problem Formulation

In the PAC formalism, the starting point is the premise that there is an unknown set, say an unknown convex polygon, or an unknown half-plane. The unknown set cannot be *completely* unknown; rather, something should be specified about its nature, in order for the problem to be both meaningful and tractable. For instance, in the first example above, the learner knows that the unknown set is a convex polygon, though it is not known *which* polygon it might be.

Similarly, in the second example, the learner knows that the unknown set is a half-plane, though it is not known *which* half-plane. The collection of all possible unknown sets is known as the **concept class**, and the particular unknown set is referred to as the "target concept." In the first example, this would be the set of all convex polygons and in the second case it would be the set of half-planes. The unknown set cannot be directly observed of course; otherwise, there would be nothing to learn. Rather, one is given clues about the target concept by an "oracle," which informs the learner whether or not a particular element belongs to the target concept. Therefore, the information available to the learner is a collection of "labelled samples," in the form $\{(x_i, I_T(x_i), i = 1, \ldots, m\}$, where m is the total number of labelled samples and $I_t(\cdot)$ is the indicator function of the target concept T. Based on this information, the learner is expected to generate a "hypothesis" H_m that is a good approximation to the unknown target concept T.

One of the main features of PAC learning theory that distinguishes it from its forerunners is the observation that, no matter how many training samples are available to the learner, the hypothesis H_m can never *exactly equal* the unknown target concept T. Rather, all that one can expect is that H_m converges to T in some appropriate metric. Since the purpose of machine learning is to generate a hypothesis H_m that can be used to approximate the unknown target concept T for prediction purposes, a natural candidate for the metric that measures the disparity between H_m and T is the so-called generalization error, defined as follows: Suppose that, after m training samples that have led to the hypothesis H_m, a testing sample x is generated at random. One can now ask: what is the probability that the hypothesis H_m misclassifies x? In other words, what is the value of $\Pr\{I_{H_m}(x) \neq I_T(x)\}$? This quantity is known as the generalization error, and the objective is to ensure that it approaches zero as $m \to \infty$.

The manner in which the samples are generated leads to different models of learning. For instance, if the learner is able to choose the next sample x_{m+1} on the basis of the previous

m labelled samples, which is then passed on to the oracle for labeling, this is known as "active learning." More common is "passive learning," in which the sequence of training samples $\{x_i\}_{i \geq 1}$ is generated at random, in an independent and identically distributed (i.i.d.) fashion, according to some probability distribution P. In this case, even the hypothesis H_m and the generalization error are random, because they depend on the randomly generated training samples. This is the rationale behind the nomenclature "probably approximately correct." The hypothesis H_m is not expected to equal to unknown target concept T exactly, only approximately. Even that is only probably true, because in principle it is possible that the randomly generated training samples could be totally unrepresentative and thus lead to a poor hypothesis. If we toss a coin many times, there is a small but always positive probability that it could turn up heads every time. As the coin is tossed more and more times, this probability becomes smaller, but will never equal zero.

Examples

Example 1 Consider the situation where the concept class consists of all half-planes in $\mathbb{R}^2$, as indicated in the left side of Fig. 1. Here the unknown target concept T is some fixed but unknown half-plane. The symbol T is next to the boundary of the half-plane, and all points to the right of the line constitute the target half-plane. The training samples, generated at random according some unknown probability distribution P, are also shown in the figure. The samples that belong to T are shown as blue rectangles, while those that do not belong to T are shown as red dots. Knowing only these labelled samples, the learner is expected to guess what T might be.

A reasonable approach is to choose some half-plane that agrees with the data and correctly classifies the labelled data. For instance, the well-known support vector machine (SVM) algorithm chooses the unique half-plane such that the closest sample to the dividing line is as far as possible from it; see the paper by Cortes and Vapnik (1997).

The symbol H denotes the boundary of a hypothesis, which is another half-plane. The shaded region is the **symmetric difference** between the two half-planes. The set $T \Delta H$ is the set of points that are misclassified by the hypothesis H. Of course, we do not know what this set is, because we do not know T. It can be shown that, whenever the hypothesis H is chosen to be **consistent** in the sense of correctly classifying all labelled samples, the generalization error goes to zero as the number of samples approaches infinity.

Example 2 Now suppose the concept class consists of all convex polygons in the unit square, and let T denote the (unknown) target convex polygon. This situation is depicted in the right side of Fig. 1. This time let us assume that the probability distribution that generates the samples is the uniform distribution on X. Given a set of positively and negatively labelled samples (the same convention as in Example 1), let us choose the hypothesis H to be the convex hull of all positively labelled samples, as shown in the figure. Since every positively labelled sample

VC dimension illustrations.
(**a**) Shattering a set of three
elements. (**b**) Infinite VC
dimension
belongs to T, and T is a convex set, it follows
that H is a subset of T. Moreover, $P(T \setminus H)$
is the generalization error. It can be shown that
this algorithm also "works" in the sense that the
generalization error goes to zero as the number of
samples approaches infinity.

Vapnik-Chervonenkis Dimension

Given any concept class $\mathcal{C}$, there is a single
integer that offers a measure of the richness of
the class, known as the Vapnik-Chervonenkis (or
VC) dimension, after its originators.

Definition 1 A set $S \subseteq X$ is said to be **shattered**
by a concept class $\mathcal{C}$ if, for every subset $B \subseteq S$,
there is a set $A \in \mathcal{C}$ such that $S \cap A = B$. The
VC dimension of $\mathcal{C}$ is the largest integer d such
that there is a finite set of cardinality d that is
shattered by $\mathcal{C}$.

Example 3 It can be shown that the set of half-
planes in $\mathbb{R}^2$ has VC dimension two. Choose a
set $S = \{x, y, z\}$ consisting of three points that
are not collinear, as in Fig. 2. Then there are
$2^3 = 8$ subsets of S. The point is to show that
for each of these eight subsets, there is a half-
plane that contains precisely that subset, nothing
more and nothing less. That this is possible is
shown in Fig. 2. Four out of the eight situations
are depicted in this figure, and the remaining four
situations can be covered by taking the comple-
ment of the half-plane shown. It is also necessary
to show that *no set with four or more elements
can be shattered*, but that step is omitted; instead

the reader is referred to any standard text such
as Vidyasagar (1997). More generally, it can be
shown that the set of half-planes in $\mathbb{R}^k$ has VC
dimension $k + 1$.

Example 4 The set of convex polygons has infi-
nite VC dimension. To see this, let S be a strictly
convex set, as shown in Fig. 2b. (Recall that a
set is "strictly convex" if none of its boundary
points is a convex combination of other points in
the set.) Choose any finite collection of boundary
points, call it $S = \{x_1, \ldots, x_n\}$. If B is a
subset of S, then the convex hull of B does not
contain any other point of S, due to the strict
convexity property. Since this argument holds for
every integer n, the class of convex polygons has
infinite VC dimension.

Two Important Theorems

Out of the many important results in learning
theory, two are noteworthy.

Theorem 1 (Blumer et al. (1989)) *A concept
class is distribution-free PAC learnable if and
only if it has finite VC dimension.*

Theorem 2 (Benedek and Itai (1991)) *Suppose
P is a fixed probability distribution. Then the
concept class $\mathcal{C}$ is PAC learnable if and only if,
for every positive number ϵ, it is possible to cover
$\mathcal{C}$ by a finite number of balls of radius ϵ, with
respect to the pseudometric d_P.*

Now let us return to the two examples stud-
ied previously. Since the set of half-planes has
finite VC dimension, it is distribution-free PAC

learnable. The set of convex polygons can be shown to satisfy the conditions of Theorem 2 if P is the uniform distribution and is therefore PAC learnable. However, since it has infinite VC dimension, it follows from Theorem 1 that it is *not* distribution-free PAC learnable.

Summary and Future Directions

This brief entry presents only the most basic aspects of PAC learning theory. Many more results are known about PAC learning theory, and of course many interesting problems remain unsolved. Some of the known extensions are:

- Learning under an "intermediate" family of probability distributions $\mathcal{P}$ that is not necessarily equal to $\mathcal{P}^*$, the set of *all* distributions (Kulkarni and Vidyasagar 1997)
- Relaxing the requirement that the algorithm should work uniformly well for all target concepts and requiring instead only that it should work with high probability (Campi and Vidyasagar 2001)
- Relaxing the requirement that the training samples are independent of each other and permitting them to have Markovian dependence (Gamarnik 2003; Meir 2000) or β-mixing dependence (Vidyasagar 2003)

There is considerable research in finding alternate sets of necessary and sufficient conditions for learnability. Unfortunately, many of these conditions are unverifiable and amount to tautological restatements of the problem under study.

Lie Algebraic Methods in Nonlinear Control

Matthias Kawski

School of Mathematical and Statistical Sciences, Arizona State University, Tempe, AZ, USA

Abstract

Lie algebraic methods generalize matrix methods and algebraic rank conditions to smooth nonlinear systems. They capture the essence of noncommuting flows and give rise to noncommutative analogues of Taylor expansions. Lie algebraic

L

rank conditions determine controllability, observability, and optimality. Lie algebraic methods are also employed for state-space realization, control design, and path planning.

Keywords

Baker-Campbell-Hausdorff formula; Chen-Fliess series; Lie bracket

Definition

This article considers generally nonlinear control systems (affine in the control) of the form

$$\begin{aligned} \dot{x} &= f_0(x) + u_1 f_1(x) + \ldots u_m f_m(x) \\ y &= \varphi(x) \end{aligned} \quad (1)$$

where the state x takes values in $\mathbb{R}^n$, or more generally in an n-dimensional manifold M^n, the f_i are smooth vector fields, $\varphi: \mathbb{R}^n \mapsto \mathbb{R}^p$ is a smooth output function, and the controls $u = (u_1, \ldots, u_m): [0, T] \mapsto U$ are piecewise continuous, or, more generally, measurable functions taking values in a closed convex subset $U \subseteq R^m$ that contains 0 in its interior.

Lie algebraic techniques refers to analyzing the system (1) and designing controls and stabilizing feedback laws by employing relations satisfied by iterated Lie brackets of the system vector fields f_i.

Introduction

Systems of the form (1) contain as a special case time-invariant linear systems $\dot{x} = Ax + Bu$, $y = Cx$ (with constant matrices $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, and $C \in \mathbb{R}^{p \times n}$) that are well-studied and are a mainstay of classical control engineering. Properties such as controllability, stabilizability, observability, and optimal control and various others are determined by relationships satisfied by higher-order matrix products of A, B, and C.

Since the early 1970s, it has been well understood that the appropriate generalization of

this matrix algebra, and, e.g., invariant linear subspaces, to nonlinear systems is in terms of the Lie algebra generated by the vector fields f_i, integral submanifolds of this Lie algebra, and the algebra of iterated Lie derivatives of the output function.

The Lie bracket of two smooth vector fields $f, g: M \mapsto TM$ is defined as the vector field $[f, g]: M \mapsto TM$ that maps any smooth function $\varphi \in C^\infty(M)$ to the function $[f, g]\varphi = fg\varphi - gf\varphi$.

In local coordinates, if

$$f(x) = \sum_{i=1}^n f^i(x) \frac{\partial}{\partial x^i} \quad \text{and}$$

$$g(x) = \sum_{i=1}^n g^i(x) \frac{\partial}{\partial x^i},$$

then

$$\begin{aligned} [f, g](x) &= \sum_{i,j=1}^n \left(f^j(x) \frac{\partial g^i}{\partial x^j}(x) \right. \\ &\qquad \left. -g^j(x) \frac{\partial f^i}{\partial x^j}(x) \right) \frac{\partial}{\partial x^i}. \end{aligned}$$

With some abuse of notation, one may abbreviate this to $[f, g] = (Dg)f - (Df)g$, where f and g are considered as column vector fields and Df and Dg denote their Jacobian matrices of partial derivatives.

Note that with this convention the Lie bracket corresponds to the negative of the commutator of matrices: If $P, Q \in \mathbb{R}^{n \times n}$ define, in matrix notation, the linear vector fields $f(x) = Px$ and $g(x) = Qx$, then $[f, g](x) = (QP - PQ)x = -[P, Q]x$.

Noncommuting Flows

Geometrically the Lie bracket of two smooth vector fields f_1 and f_2 is an infinitesimal measure of the lack of commutativity of their flows. For a smooth vector field f and an initial point $x(0) = p \in M$, denote by $e^{tf} p$ the solution of the differential equation $\dot{x} = f(x)$ at time t. Then

$$[f_1, f_2]\varphi(p) = \lim_{t \to 0} \frac{1}{2t^2} \left(\varphi \left(e^{-tf_2} e^{-tf_1} e^{tf_2} e^{tf_1} p \right) - \varphi(p) \right).$$

As a most simple example, consider parallel parking a unicycle, moving it sideways without slipping. Introduce coordinates (x, y, θ) for the location in the plane and the steering angle. The dynamics are governed by $\dot{x} = u_1 \cos \theta$, $\dot{y} = u_1 \sin \theta$, and $\dot{\theta} = u_2$ where the control u_1 is interpreted as the signed rolling speed and u_2 as the angular velocity of the steering angle. Written in the form (1), one has $f_1 = (\cos \theta, \sin \theta, 0)^T$ and $f_2 = (0, 0, 1)^T$. (In this case the drift vector field $f_0 \equiv 0$ vanishes.) If the system starts at $(0, 0, 0)^T$, then via the sequence of control actions of the form *turn left*, *roll forward*, *turn back*, and *roll backwards*, one may steer the system to a point $(0, \Delta y, 0)^T$ with $\Delta y > 0$. This sideways motion corresponds to the value $(0, 1, 0)^T$ of the Lie bracket $[f_1, f_2] = (-\sin \theta, \cos \theta, 0)^T$ at the origin. It encapsulates that steering and rolling do not commute. This example is easily expanded to model, e.g., the sideways motion of a car, or a truck with multiple trailers; see, e.g., Bloch (2003), Bressan and Piccoli (2007), and Bullo and Lewis (2005). In such cases longer iterated Lie brackets correspond to the required more intricate control actions needed to obtain, e.g., a pure sideways motion.

In the case of linear systems, if the Kalman rank condition $\text{rank}[B, AB, A^2B, \ldots A^{n-1}B] = n$ is not satisfied, then all solutions curves of the system starting from the same point $x(0) = p$ are at all times $T > 0$ constrained to lie in a proper affine subspace. In the nonlinear setting the role of the compound matrix of that condition is taken by the Lie algebra $L = L(f_0, f_1, \ldots f_m)$ of all finite linear combinations of iterated Lie brackets of the vector fields f_i. As an immediate consequence of the Frobenius integrability theorem, if at a point $x(0) = p$ the vector fields in L span the whole tangent space, then it is possible to reach an open neighborhood of the initial point by concatenating flows of the system (1) that correspond to piecewise constant controls. Conversely, in the case of analytic vector fields and a compact set U of admissible control values, the Hermann-Nagano theorem guarantees that if the dimension of the subspace $L(p) = \{f(p) : f \in L\} < n$ is not maximal, then all such trajectories are confined to stay in a lower-dimensional proper integral submanifold of L through the point p. For a comprehensive introduction, see, e.g., the textbooks Bressan and Piccoli (2007), Isidori (1995), and Sontag (1998).

Controllability

Define the reachable set $\mathcal{R}_T(p)$ as the set of all terminal points $x(T; u, p)$ at time T of trajectories of (1) that start at the initial point $x(0) = p$ and correspond to admissible controls. Commonly known as the *Lie algebra rank condition* (LARC), the above condition determines whether the system is accessible from the point p, which means that for arbitrarily small time $T > 0$, the reachable set $\mathcal{R}_T(p)$ has nonempty n-dimensional interior. For most applications one desires stronger controllability properties. Most amenable to Lie algebraic methods, and practically relevant, is small-time local controllability (STLC): The system is STLC from p if p lies in the interior of $\mathcal{R}_T(p)$ for every $T > 0$. In the case that there is no drift vector field f_0, accessibility is equivalent to STLC. However, in general, the situation is much more intricate, and a rich literature is devoted to various necessary or sufficient conditions for STLC. A popular such condition is the Hermes condition. For this define the subspaces $\mathcal{S}^1 = \text{span}\{(\text{ad}^j f_0, f_i) : 1 \leq j \leq m, \ j \in \mathbb{Z}^+\}$, and recursively $\mathcal{S}^{k+1} = \text{span}\{[g_1, g_k] : g_1 \in \mathcal{S}^1, \ g_k \in \mathcal{S}^k\}$. Here $(ad^0 f, g) = g$, and recursively $(ad^{k+1} f, g) = [f, (ad^k f, g)]$. The Hermes condition guarantees in the case of analytic vector fields and, e.g., $U = [-1, 1]^m$ that if the system satisfies the (LARC) and for every $k \geq 1$, $\mathcal{S}^{2k}(p) \subseteq \mathcal{S}^{2k-1}(p)$, then the system is (STLC). For more general conditions, see Sussmann (1987) and also Kawski (1990) for a broader discussion.

The importance and value of Lie algebraic conditions may in large part be ascribed to their geometric character, their being invariant under

coordinate changes and feedback. In particular, in the analytic case, the Lie relations completely determine the local properties of the system, in the sense that Lie algebra homomorphism between two systems gives rise to a local diffeomorphism that maps trajectories to trajectories (Sussmann 1974).

Exponential Lie Series

A central analytic tool in Lie algebraic methods that takes the role of Taylor expansions in classical analysis of dynamical system is the Chen-Fliess series which associates to every admissible control $u: [0, T] \mapsto U$ a formal power series

$$\mathrm{CF}(u, T) = \sum_I \int_0^T du^I \cdot X_{i_1} \dots X_{i_s} \quad (2)$$

over a set $\{X_0, X_1, \dots X_m\}$ of noncommuting indeterminates (or *letters*). For every multi-index $I = (i_1, i_2, \dots 1_s) \in \{0, 1, \dots m\}^s$, $s \geq 0$, the coefficient of X_I is the iterated integral defined recursively

$$\int_0^T du^{(I,j)} = \int_0^T \left(\int_0^t u^I \right) du_j(t). \quad (3)$$

Upon evaluating this series via the substitutions $X_i \longleftarrow f_j$, it becomes an *asymptotic series for the propagation of solutions of* (1): For f_j, φ analytic, U compact, p in a compact set, and $T \geq 0$ sufficiently small, one has

$$\varphi(x(t; u, p)) = \sum_I \int_0^T du^I \cdot (f_{i_1} \dots f_{i_s} \varphi)(p). \quad (4)$$

One application of particular interest is to construct approximating systems of a given system (1) that preserve critical geometric properties, but which have an simpler structure. One such class is that of nilpotent systems, that is, systems whose Lie algebra $L = L(f_0, f_1, \dots f_m)$ is nilpotent, and for which solutions can be found by simple quadratures. While truncations of the Chen-Fliess series

never correspond to control systems of the same form, much work has been done in recent years to rewrite this series in more useful formats. For example, the infinite directed exponential product expansion in Sussmann (1986) that uses Hall trees immediately may be interpreted in terms of free nilpotent systems and consequently helps in the construction of nilpotent approximating systems. More recent work, much of it of a combinatorial algebra nature and utilizing the underlying Hopf algebras, further simplifies similar expansions and in particular yields explicit formulas for a continuous Baker-Campbell-Hausdorff formula or for the logarithm of the Chen-Fliess series (Gehrig and Kawski 2008).

Observability and Realization

In the setting of linear systems a well-defined algebraic sense dual to the concept of controllability is that of observability. Roughly speaking the system (1) is observable if knowledge of the output $y(t) = \varphi(x(t; u, p))$ over an arbitrarily small interval suffices to construct the current state $x(t; u, p)$ and indeed the past trajectory $x(\,\cdot\,; u, p)$. In the linear setting observability is equivalent to the rank condition $\mathrm{rank}[C^T, (CA)^T, \dots, (CA^{n-})^T] = n$ being satisfied. In the nonlinear setting, the place of the rows of this compound matrix is taken by the functions in the observation algebra, which consists of all finite linear combinations of iterated Lie derivatives $f_{i_s} \cdots f_{i_1} \varphi$ of the output function.

Similar to the Hankel matrices introduced in the latter setting, in the case of a finite Lie rank, one again can use the output algebra to construct realizations in the form of (1) for systems which are initially only given in terms of input-output descriptions, or in terms of formal Fliess operators; see, e.g., Fliess (1980), Gray and Wang (2002), and Jakubczyk (1986) for further reading.

Optimal Control

In a well-defined geometric way, conditions for optimal control are dual to conditions for controllability and thus are directly amenable to Lie algebraic methods. Instead of considering a separate functional

$$J(u) = \psi(x(T; u, p)) + \int_0^T L(t, x(t; u, p), u(t)) \, dt$$

(5)

to be minimized, it is convenient for our purposes to augment the state by, e.g., defining $\dot{x}_0 = 1$ and $\dot{x}_{n+1} = L(x_0, x, u)$. For example, in the case of time-optimal control, one again obtains an enlarged system of the same form (1); else one utilizes more general Lie algebraic methods that also apply to systems not necessarily affine in the control.

The basic picture for systems with a compact set U of admissible values of the controls involves the attainable funnel $\mathcal{R}_{\leq T}(p)$ consisting of all trajectories of the system (1) starting at $x(0) = p$ that correspond to admissible controls. The trajectory corresponding to an optimal control u^* must at time T lie on the boundary of the funnel $\mathcal{R}_{\leq T}(p)$ and hence also at all prior times (using the invariance of domain property implied by the continuity of the flow). Hence one may associate a covector field along such optimal trajectory that at every time points in the direction of an outward normal. The Pontryagin Maximum Principle is a first-order characterization of such trajectory covector field pairs. Its pointwise maximization condition essentially says that if at any time $t_0 \in [0, T]$ one replaces the optimal control $u^*(\cdot)$ by any admissible control variation on an interval $[t_0, t_0 + \varepsilon]$, then such variation may be transported along the flow to yield, in the limit as $\varepsilon \searrow 0$, an *inward* pointing tangent vector to the reachable set $\mathcal{R}_T(p)$ at $x(T; u^*, p)$. To obtain stronger higher-order conditions for maximality, one may combine several such families of control variations. The effects of such combinations are again calculated in terms of iterated Lie brackets of the vector fields f_i. Indeed, necessary conditions for optimality, for a trajectory to lie on the boundary of the funnel $\mathcal{R}_{\leq T}(p)$, immediately translate into sufficient conditions for STLC, for the initial point to lie in the interior of $\mathcal{R}_T(p)$, and vice versa. For recent work employing Lie algebraic methods in optimality conditions, see, e.g., Agrachev et al. (2002).

Summary and Future Research

Lie algebraic techniques may be seen as a direct generalization of matrix linear algebra tools that have proved so successful in the analysis and design of linear systems. However, in the nonlinear case, the known algebraic rank conditions still exhibit gaps between necessary and sufficient conditions for controllability and optimality. Also, new, not yet fully understood, topological and resonance obstructions stand in the way of controllability implying stabilizability. Systems that exhibit special structure, such as living on Lie groups, or being second order such as typical mechanical systems, are amenable to further refinements of the theory; compare, e.g., the use of affine connections and the symmetric product in Bullo et al. (2000). Other directions of ongoing and future research involve the extension of Lie algebraic methods to infinite dimensional systems and to generalize formulas to systems with less regularity; see, e.g., the work by Rampazzo and Sussmann (2007) on Lipschitz vector fields, thereby establishing closer connections with nonsmooth analysis (Clarke 1983) in control.

Linear Matrix Inequality Techniques in Optimal Control

Robert E. Skelton
University of California, San Diego, CA, USA

Abstract

LMI (linear matrix inequality) techniques offer more flexibility in the design of dynamic linear systems than techniques that minimize a scalar functional for optimization. For linear state space models, multiple goals (performance bounds) can be characterized in terms of LMIs, and these can serve as the basis for controller optimization via finite-dimensional convex feasibility problems. LMI formulations of various standard control problems are described in this article, including dynamic feedback stabilization, covariance control, LQR, H_∞ control, L_∞ control, and information architecture design.

Keywords

Control system design; Covariance control; H_∞ control; L_∞ control; LQR/LQG; Matrix inequalities; Sensor/actuator design

Early Optimization History

Hamilton invented state space models of nonlinear dynamic systems with his generalized momenta work in the 1800s (Hamilton 1834, 1835), but at that time the lack of computational tools prevented broad acceptance of the first-order form of dynamic equations. With the rapid development of computers in the 1960s, state space models evoked a formal control theory for minimizing a scalar function of control and state, propelled by the calculus of variations and Pontryagin's maximum principle. Optimal control has been a pillar of control theory for the last 50 years. In fact, all of the problems discussed in this article can perhaps be solved

by minimizing a scalar functional, but a search is required to find the right functional. Globally convergent algorithms are available to do just that for quadratic functionals, but more direct methods are now available.

Since the early 1990s, the focus for linear system design has been to pose control problems as feasibility problems, to satisfy multiple constraints. Since then, feasibility approaches have dominated design decisions, and such feasibility problems may be convex or not. If the problem can be reduced to a set of linear matrix inequalities (LMIs) to solve, then convexity is proven. However, failure to find such LMI formulations of the problem does not mean it is not convex, and computer-assisted methods for convex problems are available to avoid the search for LMIs (see Camino et al. 2003).

In the case of linear dynamic models of stochastic processes, optimization methods led to the popularization of linear quadratic Gaussian (LQG) optimal control, which had globally optimal solutions (see Skelton 1988). The first two moments of the stochastic process (the mean and the covariance) can be controlled with these methods, even if the distribution of the random variables involved is not Gaussian. Hence, LQG became just an acronym for the solution of quadratic functionals of control and state variables, even when the stochastic processes were not Gaussian. The label LQG was often used even for deterministic problems, where a time integral, rather than an expectation operator, was minimized, with given initial conditions or impulse excitations. These were formally called LQR (linear quadratic regulator) problems. Later the book (Skelton 1988) gave the formal conditions under which the LQG and the LQR answers were numerically identical, and this particular version of LQR was called the *deterministic LQG*.

It was always recognized that the quadratic form of the state and control in the LQG problem was an artificial goal. The real control goals usually involved prespecified performance bounds on *each* of the outputs and bounds on *each* channel of control. This leads to matrix inequalities (MIs) rather than scalar minimizations. While

it was known early that *any* stabilizing linear controller could be obtained by some choice of weights in an LQG optimization problem (see Chap. 6 and references in Skelton 1988), it was not known until the 1980s *what* particular choice of weights in LQG would yield a solution to the matrix inequality (MI) problem. See early attempts in Skelton (1988), and see Zhu and Skelton (1992) and Zhu et al. (1997) for a globally convergent algorithm to find such LQG weights when the MI problem has a solution. Since then, rather than stating a minimization problem for a meaningless sum of outputs and inputs, linear control problems can now be stated simply in terms of norm bounds on *each* input vector and/or *each* output vector of the system (L_2 bounds, L_∞ bounds, or variance bounds and covariance bounds). These *feasibility* problems are convex for state feedback or full-order output feedback controllers (the focus of this elementary introduction), and these can be solved using linear matrix inequalities (LMIs), as illustrated in this article. However, the earliest approach to these MI problems was iterative LQG solutions (to find the correct weights to use in the quadratic penalty of the state), as in Skelton (1988), Zhu and Skelton (1992), and Zhu et al. (1997).

Matrix Inequalities

Let $\mathbf{Q}$ be any square matrix. The linear matrix inequality (LMI) "$\mathbf{Q} > \mathbf{0}$" is just a short-hand notation to represent a certain scalar inequality. That is, the matrix notation "$\mathbf{Q} > \mathbf{0}$" means "the scalar $\mathbf{x^T Q x}$ is positive for all values of $\mathbf{x}$, except $\mathbf{x} = \mathbf{0}$." Obviously this is a property of $\mathbf{Q}$, not $\mathbf{x}$, hence the abbreviated matrix notation $\mathbf{Q} > \mathbf{0}$. This is called a linear matrix inequality (LMI), since the matrix unknown $\mathbf{Q}$ appears linearly in the inequality $\mathbf{Q} > \mathbf{0}$. Note also that any square matrix $\mathbf{Q}$ can be written as the sum of a symmetric matrix $\mathbf{Q_s} = \frac{1}{2}(\mathbf{Q} + \mathbf{Q^T})$, and a skew-symmetric matrix $\mathbf{Q_k} = \frac{1}{2}(\mathbf{Q} - \mathbf{Q^T})$, but $\mathbf{x^T Q_k x} = \mathbf{0}$, so only the symmetric part of the matrix $\mathbf{Q}$ affects the scalar $\mathbf{x^T Q x}$. We assume hereafter without loss of generality that $\mathbf{Q}$ is

L

symmetric. The notation "$\mathbf{Q} \geq \mathbf{0}$" means "the scalar $\mathbf{x^TQx}$ cannot be negative for any $\mathbf{x}$."

Lyapunov proved that $\mathbf{x(t)}$ converges to zero if there exists a matrix $\mathbf{Q}$ such that, along the nonzero trajectory of a dynamic system (e.g., the system $\dot{\mathbf{x}} = \mathbf{Ax}$), two scalars have the property, $\mathbf{x(t)^TQx(t)} > 0$ and $d/dt(\mathbf{x^T(t)Qx(t)}) < 0$. This proves that the following statements are all equivalent:

1. For any initial condition $\mathbf{x(0)}$ of the system $\dot{\mathbf{x}} = \mathbf{Ax}$, the state $\mathbf{x(t)}$ converges to zero.
2. All eigenvalues of $\mathbf{A}$ lie in the open left half plane.
3. There exists a matrix $\mathbf{Q}$ with the two properties $\mathbf{Q} > \mathbf{0}$ and $\mathbf{QA + A^TQ < 0}$.
4. The set of all quadratic Lyapunov functions that can be used to prove the stability or instability of the null solution of $\dot{\mathbf{x}} = \mathbf{Ax}$ is given by $\mathbf{x^TQ^{-1}x}$, where $\mathbf{Q}$ is any square matrix with the two properties of item 3 above.

LMIs are prevalent throughout the fundamental concepts of control theory, such as controllability and observability. For the linear system example $\dot{\mathbf{x}} = \mathbf{Ax + Bu}$, $\mathbf{y} = \mathbf{Cx}$, the "Observability Gramian" is the infinite integral $\mathbf{Q} = \int \mathbf{e^{A^Tt}C^TCe^{At}dt}$. Furthermore $\mathbf{Q} > \mathbf{0}$ if and only if $(\mathbf{A, C})$ is an observable pair, and $\mathbf{Q}$ is bounded only if the observable modes are asymptotically stable. When it exists, the solution of $\mathbf{QA + A^TQ + C^TC = 0}$ satisfies $\mathbf{Q} > \mathbf{0}$ if and only if the matrix pair $(\mathbf{A, C})$ is observable.

Likewise the "Controllability Gramian" $\mathbf{X} = \int \mathbf{e^{At}BB^Te^{A^Tt}dt} > \mathbf{0}$ if and only if the pair $(\mathbf{A, B})$ is controllable. If $\mathbf{X}$ exists, it satisfies $\mathbf{XA^T + AX + BB^T = 0}$, and $\mathbf{X} > \mathbf{0}$ if and only if $(\mathbf{A, B})$ is a controllable pair. Note also that the matrix pair $(\mathbf{A, B})$ is controllable for any $\mathbf{A}$ if $\mathbf{BB^T > 0}$, and the matrix pair $(\mathbf{A, C})$ is observable for any $\mathbf{A}$ if $\mathbf{C^TC > 0}$. Hence, the existence of $\mathbf{Q} > \mathbf{0}$ or $\mathbf{X} > \mathbf{0}$ satisfying either $(\mathbf{QA + A^TQ < 0})$ or $(\mathbf{AX + XA^T < 0})$ is equivalent to the statement that "all eigenvalues of $\mathbf{A}$ lie in the open left half plane."

It should now be clear that the set of all stabilizing state feedback controllers, $\mathbf{u = Gx}$, is parametrized by the inequalities $\mathbf{Q} > \mathbf{0}$, $\mathbf{Q(A + BG) + (A + BG)^TQ < 0}$. The difficulty in this

MI is the appearance of the product of the two unknowns $\mathbf{Q}$ and $\mathbf{G}$, so more work is required to show how to use LMIs to solve this problem.

In the sequel some techniques are borrowed from linear algebra, where a linear matrix equality (LME) $\mathbf{\Gamma G\Lambda = \Theta}$ may or may not have a solution $\mathbf{G}$. For LMEs there are two separate questions to answer. The first question is "Does there exist a solution?" and the answer is "if and only if $\mathbf{\Gamma\Gamma^+\Theta\Lambda^+\Lambda = \Theta}$." The second question is "What is the set of all solutions?" and the answer is "$\mathbf{G = \Gamma^+\Theta\Lambda^+ + Z - \Gamma^+\Gamma Z\Lambda\Lambda^+}$, where $\mathbf{Z}$ is arbitrary, and the $+$ symbol denotes Pseudo Inverse." LMI approaches employ the same two questions by formulating the necessary and sufficient conditions for the existence of an LMI solution and then to parametrize all solutions.

Perhaps the earliest book on LMI control methods was Boyd et al. (1994), but the results and notations used herein are taken from Skelton et al. (1998). Other important LMI papers and books can give the reader a broader background, including Iwasaki and Skelton (1994), Gahinet and Apkarian (1994), de Oliveira et al. (2002), Li et al. (2008), de Oliveira and Skelton (2001), Camino et al. (2001, 2003), Boyd and Vandenberghe (2004), Iwasaki et al. (2000), Khargonekar and Rotea (1991), Vandenberghe and Boyd (1996), Scherer (1995), Scherer et al. (1997), Balakrishnan et al. (1994), Gahinet et al. (1995), and Dullerud and Paganini (2000).

Control Design Using LMIs

Consider the feedback control system

$$\begin{bmatrix} \mathbf{\dot{x}_p} \\ \mathbf{y} \\ \mathbf{z} \end{bmatrix} = \begin{bmatrix} \mathbf{A_p} & \mathbf{D_p} & \mathbf{B_p} \\ \mathbf{C_p} & \mathbf{D_y} & \mathbf{B_y} \\ \mathbf{M_p} & \mathbf{D_z} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{x_p} \\ \mathbf{w} \\ \mathbf{u} \end{bmatrix},$$

$$\begin{bmatrix} \mathbf{u} \\ \mathbf{\dot{x}_c} \end{bmatrix} = \begin{bmatrix} \mathbf{D_c} & \mathbf{C_c} \\ \mathbf{B_c} & \mathbf{A_c} \end{bmatrix} \begin{bmatrix} \mathbf{z} \\ \mathbf{x_c} \end{bmatrix} = \mathbf{G} \begin{bmatrix} \mathbf{z} \\ \mathbf{x_c} \end{bmatrix}, \quad (1)$$

where $\mathbf{z}$ is the measurement vector, $\mathbf{y}$ is the output to be controlled, $\mathbf{u}$ is the control vector, $\mathbf{x_p}$ is the plant state vector, $\mathbf{x_c}$ is the state of the controller,

and **w** is the external disturbance (in some cases below we treat **w** as a zero-mean white noise). We seek to choose the control matrix **G** to satisfy the given upper bounds on the output covariance $E[\mathbf{yy^T}] \leq \bar{\mathbf{Y}}$, where E represents the steady-state expectation operator in the stochastic case (i.e., when **w** is white noise), and in the deterministic case E represents the infinite integral of the matrix $[\mathbf{yy^T}]$. The math is the same in each case, with appropriate interpretations of certain matrices. For a rigorous equivalence of the deterministic and stochastic interpretations, see Skelton (1988). By defining the matrices,

$$\mathbf{x} = \begin{bmatrix} \mathbf{x_p} \\ \mathbf{x_c} \end{bmatrix},$$

$$\begin{bmatrix} \mathbf{A_{cl}} & \mathbf{B_{cl}} \\ \mathbf{C_{cl}} & \mathbf{D_{cl}} \end{bmatrix} = \begin{bmatrix} \mathbf{A} & \mathbf{D} \\ \mathbf{C} & \mathbf{F} \end{bmatrix} + \begin{bmatrix} \mathbf{B} \\ \mathbf{H} \end{bmatrix} \mathbf{G} \begin{bmatrix} \mathbf{M} & \mathbf{E} \end{bmatrix} \quad (2)$$

$$\mathbf{A} = \begin{bmatrix} \mathbf{A_p} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} \mathbf{B_p} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix},$$

$$\mathbf{M} = \begin{bmatrix} \mathbf{M_p} & \mathbf{I} \\ \mathbf{0} & \mathbf{I} \end{bmatrix}, \quad \mathbf{D} = \begin{bmatrix} \mathbf{D_p} \\ \mathbf{0} \end{bmatrix}, \quad \mathbf{E} = \begin{bmatrix} \mathbf{D_z} \\ \mathbf{0} \end{bmatrix}$$
(3)

$$\mathbf{C} = \begin{bmatrix} \mathbf{C_p} & \mathbf{0} \end{bmatrix}, \quad \mathbf{H} = \begin{bmatrix} \mathbf{B_y} & \mathbf{0} \end{bmatrix}, \quad \mathbf{F} = \mathbf{D_y}, \quad (4)$$

one can write the closed-loop system dynamics in the form

$$\begin{bmatrix} \dot{\mathbf{x}} \\ \mathbf{y} \end{bmatrix} = \begin{bmatrix} \mathbf{A_{cl}} & \mathbf{B_{cl}} \\ \mathbf{C_{cl}} & \mathbf{D_{cl}} \end{bmatrix} \begin{bmatrix} \mathbf{x} \\ \mathbf{w} \end{bmatrix}. \quad (5)$$

Often it is of interest to characterize the set of all controllers that can satisfy performance bounds on both the outputs and inputs, $E[\mathbf{yy^T}] \leq \bar{\mathbf{Y}}$ and $E[\mathbf{uu^T}] \leq \bar{\mathbf{U}}$, and we call these *covariance* control problems. But without prespecified performance bounds $\bar{\mathbf{Y}}, \bar{\mathbf{U}}$, one can require stability only. Such examples are given below.

Many Control Problems Reduce to the Same LMI

Let the left (right) null spaces of any matrix **B** be defined by matrices $\mathbf{U_B}$ ($\mathbf{V_B}$), where $\mathbf{U_B^T B} = \mathbf{0}$, $\mathbf{U_B^T U_B} > \mathbf{0}$, ($\mathbf{BV_B} = \mathbf{0}$, $\mathbf{V_B^T V_B} > \mathbf{0}$). For

any given matrices $\mathbf{\Gamma}, \mathbf{\Lambda}, \mathbf{\Theta}$, Chap. 9 of the book (Skelton et al. 1998) provides all **G** which solve

$$\mathbf{\Gamma G \Lambda} + (\mathbf{\Gamma G \Lambda})^\mathbf{T} + \mathbf{\Theta} < \mathbf{0}, \quad (6)$$

and proves that there exists such a matrix **G** if and only if the following two conditions hold:

$$\mathbf{U_\Gamma^T \Theta} U_\mathbf{\Gamma} < \mathbf{0}, \quad \text{or} \quad \mathbf{\Gamma \Gamma^T} > \mathbf{0}, \quad (7)$$

$$\mathbf{V_\Lambda^T \Theta} V_\mathbf{\Lambda} < \mathbf{0}, \quad \text{or} \quad \mathbf{\Lambda^T \Lambda} > \mathbf{0}. \quad (8)$$

If **G** exists, then one set of such **G** is given by

$$\mathbf{G} = -\rho\mathbf{\Gamma^T \Phi \Lambda^T} (\mathbf{\Lambda \Phi \Lambda^T})^{-1}, \ \mathbf{\Phi} = (\rho\mathbf{\Gamma \Gamma^T} - \mathbf{\Theta})^{-1},$$
(9)

where $\rho > 0$ is an arbitrary scalar such that

$$\mathbf{\Phi} = (\rho\mathbf{\Gamma \Gamma^T} - \mathbf{\Theta})^{-1} > \mathbf{0}. \quad (10)$$

All **G** which solve the problem are given by Theorem 2.3.12 in Skelton et al. (1998). As elaborated in Chap. 9 of Skelton et al. (1998), 17 different control problems (using either state feedback or full-order dynamic controllers) all reduce to this same mathematical problem. That is, by defining the appropriate $\mathbf{\Theta}, \mathbf{\Lambda}, \mathbf{\Gamma}$, a very large number of different control problems, including the characterization of all stabilizing controllers, covariance control, H-infinity control, L-infinity control, LQG control, and H_2 control, can be reduced to the *same* matrix inequality (13). Several examples from Skelton et al. (1998) follow.

Stabilizing Control
There exists a controller **G** that stabilizes the system (1) if and only if (7) and (8) hold, where the matrices are defined by

$$\begin{bmatrix} \mathbf{\Gamma} & \mathbf{\Lambda^T} & \mathbf{\Theta} \end{bmatrix} = \begin{bmatrix} \mathbf{B} & \mathbf{XM^T} & \mathbf{AX} + \mathbf{XA^T} \end{bmatrix}.$$
(11)

One can also write such results in another way, as in Corollary 6.2.1 of Skelton et al. (1998, p. 135): There exists a control of the form $\mathbf{u} = \mathbf{Gx}$ that can stabilize the system $\dot{\mathbf{x}} = \mathbf{Ax} + \mathbf{Bu}$ if and only if there exists a matrix $\mathbf{X} > \mathbf{0}$

satisfying $\mathbf{B}^{\perp}(\mathbf{AX} + \mathbf{XA^T})(\mathbf{B}^{\perp})^{\mathbf{T}} < \mathbf{0}$, where $\mathbf{B}^{\perp}$ denotes the left null space of $\mathbf{B}$. In this case all stabilizing controllers may be parametrized by $\mathbf{G} = -\mathbf{B^T P} + \mathbf{L Q^{1/2}}$, for any $\mathbf{Q} > \mathbf{0}$ and a $\mathbf{P} > \mathbf{0}$ satisfying $\mathbf{PA} + \mathbf{A^T P} - \mathbf{PBB^T P} + \mathbf{Q} = \mathbf{0}$. The matrix $\mathbf{L}$ is any matrix that satisfies the norm bound $\|\mathbf{L}\| < 1$. Youla et al. (1976) provided a parametrization of the set of all stabilizing controllers, but the parametrization was infinite dimensional (as it did not impose any restriction on the order or form of the controller). So for finite calculations one had to truncate the set to a finite number before optimization or stabilization started. As noted above, on the other hand, all stabilizing state feedback controllers $\mathbf{G}$ can be parametrized in terms of an arbitrary but finite-dimensional norm-bounded matrix $\mathbf{L}$. Similar results apply for the dynamic controllers of any fixed order (see Chap. 6 in Skelton et al. 1998).

Covariance Upper Bound Control

In the system (1), suppose that $\mathbf{D_y} = \mathbf{0}$, $\mathbf{B_y} = \mathbf{0}$ and that $\mathbf{w}$ is zero-mean white noise with intensity $\mathbf{I}$. Let a required upper bound $\overline{\mathbf{Y}} > \mathbf{0}$ on the steady-state output covariance $\mathbf{Y} = E[\mathbf{yy^T}]$ be given. The following statements are equivalent:

(i) There exists a controller $\mathbf{G}$ that solves the covariance upper bound control problem $\mathbf{Y} < \overline{\mathbf{Y}}$.

(ii) There exists a matrix $\mathbf{X} > \mathbf{0}$ such that $\mathbf{Y} = \mathbf{CXC^T} < \overline{\mathbf{Y}}$ and (7) and (8) hold, where the matrices are defined by

$$\begin{bmatrix} \boldsymbol{\Gamma} & \boldsymbol{\Lambda}^{\mathbf{T}} & \boldsymbol{\Theta} \end{bmatrix}$$
$$= \begin{bmatrix} \mathbf{B} & \mathbf{XM^T} & \mathbf{AX} + \mathbf{XA^T} & \mathbf{D} \\ \mathbf{0} & \mathbf{E^T} & \mathbf{D^T} & -\mathbf{I} \end{bmatrix} \tag{12}$$

($\boldsymbol{\Theta}$ occupies the last two columns).

Proof is provided by Theorem 9.1.2 in Skelton et al. (1998).

Linear Quadratic Regulator

Consider the linear time-invariant system (1). Suppose that $\mathbf{D_y} = \mathbf{0}$, $\mathbf{D_z} = \mathbf{0}$ and that $\mathbf{w}$ is the impulsive disturbance $\mathbf{w(t)} = \mathbf{w_0}\delta(\mathbf{t})$. Let a performance bound $\gamma > 0$ be given, where

the required performance is to keep the integral squared output ($\|\mathbf{y}\|_{\mathbf{L2}}^{\mathbf{2}}$) less than the prespecified value $\|\mathbf{y}\|_{\mathbf{L2}} < \gamma$ for any vector $\mathbf{w_0}$ such that $\mathbf{w_0^T w_0} \leq \mathbf{1}$, and $\mathbf{x_0} = \mathbf{0}$. This problem is labeled linear quadratic regulator (LQR). The following statements are equivalent:

(i) There exists a controller $\mathbf{G}$ that solves the LQR problem.

(ii) There exists a matrix $\mathbf{Y} > \mathbf{0}$ such that $\|\mathbf{D^T YD}\| < \gamma^2$ and (7) and (8) hold, where the matrices are defined by

$$\begin{bmatrix} \boldsymbol{\Gamma} & \boldsymbol{\Lambda}^{\mathbf{T}} & \boldsymbol{\Theta} \end{bmatrix}$$
$$= \begin{bmatrix} \mathbf{YB} & \mathbf{M^T} & \mathbf{YA} + \mathbf{A^T Y} & \mathbf{M^T} \\ \mathbf{H} & \mathbf{0} & \mathbf{M} & -\mathbf{I} \end{bmatrix}. \tag{13}$$

Proof is provided by Theorem 9.1.3 in Skelton et al. (1998).

H_∞ Control

LMI techniques provided the first papers to solve the general H_∞ problem, without any restrictions on the plant. See Iwasaki and Skelton (1994) and Gahinet and Apkarian (1994).

Let the closed-loop transfer matrix from $\mathbf{w}$ to $\mathbf{y}$ with the controller in (1) be denoted by $\mathbf{T(s)}$:

$$\mathbf{T(s)} = \mathbf{C_{cl}(sI} - \mathbf{A_{cl})^{-1} B_{cl}} + \mathbf{D_{cl}}. \tag{14}$$

The H_∞ control problem can be defined as follows:

> Let a performance bound $\gamma > 0$ be given. Determine whether or not there exists a controller $\mathbf{G}$ in (1) which asymptotically stabilizes the system and yields the closed-loop transfer matrix (14) such that the peak value of the frequency response is less than γ. That is, $\|\mathbf{T}\|_{\mathbf{H_\infty}} = \sup \|\mathbf{T}(j\omega)\| < \gamma$.

For the H_∞ control problem, we have the following result. Let a required H_∞ performance bound $\gamma > 0$ be given. The following statements are equivalent:

(i) A controller $\mathbf{G}$ solves the H_∞ control problem.

(ii) There exists a matrix $\mathbf{X} > \mathbf{0}$ such that (7) and (8) holds, where

$$\begin{bmatrix} \boldsymbol{\Gamma} & \boldsymbol{\Lambda}^{\mathbf{T}} & \boldsymbol{\Theta} \end{bmatrix}$$
$$= \begin{bmatrix} \mathbf{B} & \mathbf{XM}^{\mathbf{T}} & \mathbf{AX} + \mathbf{XA}^{\mathbf{T}} & \mathbf{XC}^{\mathbf{T}} & \mathbf{D} \\ \mathbf{H} & \mathbf{0} & \mathbf{CX} & -\gamma\mathbf{I} & \mathbf{F} \\ \mathbf{0} & \mathbf{E}^{\mathbf{T}} & \mathbf{D}^{\mathbf{T}} & \mathbf{F}^{\mathbf{T}} & -\gamma\mathbf{I} \end{bmatrix}$$
(15)

($\boldsymbol{\Theta}$ occupies the last three columns).
Proof is provided by Theorem 9.1.5 in Skelton et al. (1998).

L_∞ Control

The peak value of the frequency response is controlled by the above H_∞ controller. A similar theorem can be written to control the peak in the time domain.

Define $\sup \mathbf{y(t)}^{\mathbf{T}}\mathbf{y(t)} = \|\mathbf{y}\|_{\mathbf{L}\infty}^2$, and let the statement $\|\mathbf{y}\|_{L\infty} < \gamma$ mean that the peak value of $\mathbf{y(t)}^{\mathbf{T}}\mathbf{y(t)}$ is less than γ^2. Suppose that $\mathbf{D_y} = \mathbf{0}$ and $\mathbf{B_y} = \mathbf{0}$. There exists a controller $\mathbf{G}$ which maintains $\|\mathbf{y}\|_{L\infty} < \gamma$ in the presence of any energy-bounded input $\mathbf{w(t)}$ (i.e., $\int_0^\infty \mathbf{w^Tw}dt \leq \mathbf{1}$) if and only if there exists a matrix $\mathbf{X} > \mathbf{0}$ such that $\mathbf{CXC^T} < \gamma^2\mathbf{I}$ and (7) and (8) hold, where

$$\begin{bmatrix} \boldsymbol{\Gamma} & \boldsymbol{\Lambda}^{\mathbf{T}} & \boldsymbol{\Theta} \end{bmatrix}$$
$$= \begin{bmatrix} \mathbf{B} & \mathbf{XM}^{\mathbf{T}} & \mathbf{AX} + \mathbf{XA}^{\mathbf{T}} & \mathbf{D} \\ \mathbf{0} & \mathbf{E}^{\mathbf{T}} & \mathbf{D}^{\mathbf{T}} & -\gamma\mathbf{I} \end{bmatrix}.$$
(16)

Proof is provided by Theorem 9.1.4 in Skelton et al. (1998).

Information Architecture in Estimation and Control Problems

In the typical "control problem" that occupies most research literature, the sensors and actuators have already been selected. Yet the selection of sensors and actuators and their locations greatly affect the ability of the control system to do its job efficiently. Perhaps in one location a high-precision sensor is needed, and in another location high precision is not needed, and paying for high precision in that location would therefore be a waste of resources. These decisions must be influenced by the control dynamics which are yet

to be designed. How does one know where to effectively spend money to improve the system? To answer this question, we must optimize the information architecture jointly with the control law.

Let us consider the problem of selecting the control law jointly with the selection of the precision (defined here as the inverse of the noise intensity) of each actuator/sensor, subject to the constraint of specified upper bounds on the covariance of output error and control signals, and specified upper bounds on the sensor/actuator cost. We assume the cost of these devices is proportional to their precision (i.e., the cost is equal to the *price per unit of precision*, times the precision). Traditionally, with full-order controllers, and *prespecified* sensor/actuator instruments (with specified precisions); this is a well-known solved convex problem (which means it can be converted to an LMI problem if desired), see Chap. 6 of Skelton et al. (1998). If we enlarge the domain of the freedom to include sensor/actuator precisions, it is not obvious whether the feasibility problem is convex or not. The following shows that this problem of including the sensor/actuator precisions within the control design problem is indeed convex and therefore completely solved. The proof is provided in Li et al. (2008).

Consider the linear control system (1)–(5). Assume that the cost of sensors and actuators is proportional to their precision, which we herein define to be the inverse of the noise intensity (or variance, in the discrete-time case). So if the price per unit of precision of the i-th sensor/actuator is P_{ii}, and if the variance (or intensity) of the noise associated with the i-th sensor/actuator is W_{ii}, then the total cost of all sensors and actuators is $\sum P_{ii}W_{ii}^{-1}$, or simply $\mathbf{tr}(\mathbf{PW^{-1}})$, where $\mathbf{P} = \mathrm{diag}(P_{ii})$ and $\mathbf{W^{-1}} = \mathrm{diag}(W_{ii}^{-1})$.

Consider the control system (1). Suppose that $\mathbf{D_y} = \mathbf{0}$, $\mathbf{B_y} = \mathbf{0}$, $\mathbf{w} = \begin{bmatrix} \mathbf{w_s^T} & \mathbf{w_a^T} \end{bmatrix}^{\mathbf{T}}$ is the zero-mean sensor/actuator noise, $\mathbf{D_p} = [\mathbf{0} \quad \mathbf{D_a}]$ and $\mathbf{D_z} = [\mathbf{D_s} \quad \mathbf{0}]$. If the $\bar{\$}$ represents the allowed upper bound on sensor/actuator costs, there exists a dynamic controller $\mathbf{G}$ that satisfies the constraints

$$E[\mathbf{uu^T}] < \bar{\mathbf{U}}, \quad E[\mathbf{yy^T}] < \bar{\mathbf{Y}}, \quad \mathbf{tr}(\mathbf{PW^{-1}}) < \bar{\$}$$
(17)

in the presence of sensor/actuator noise with intensity $\text{diag}(W_{ii}) = \mathbf{W}$ (which like $\mathbf{G}$ should be considered a design variable not fixed a priori) if and only if there exist matrices $\mathbf{L}, \mathbf{F}, \mathbf{Q}, \mathbf{X}, \mathbf{Z}, \mathbf{W^{-1}}$ such that

$$\mathbf{tr}(\mathbf{PW^{-1}}) < \bar{\$} \qquad (18)$$

$$\begin{bmatrix} \bar{\mathbf{Y}} & \mathbf{C_pX} & \mathbf{C_p} \\ (\mathbf{C_pX})^\mathbf{T} & \mathbf{X} & \mathbf{I} \\ \mathbf{C_p}^\mathbf{T} & \mathbf{I} & \mathbf{Z} \end{bmatrix} > \mathbf{0}, \quad \begin{bmatrix} \bar{\mathbf{U}} & \mathbf{L} & \mathbf{0} \\ \mathbf{L^T} & \mathbf{X} & \mathbf{I} \\ \mathbf{0} & \mathbf{I} & \mathbf{Z} \end{bmatrix} > \mathbf{0},$$

$$\begin{bmatrix} \mathbf{\Phi}_{11} & \mathbf{\Phi}_{21}^\mathbf{T} \\ \mathbf{\Phi}_{21} & -\mathbf{W^{-1}} \end{bmatrix} < 0, \qquad (19)$$

$$\mathbf{\Phi}_{21} = \begin{bmatrix} \mathbf{D_a} & \mathbf{0} \\ \mathbf{ZD_a} & \mathbf{FD_s} \end{bmatrix},$$

$$\phi = \begin{bmatrix} \mathbf{A_pX} + \mathbf{B_pL} & \mathbf{A_p} \\ \mathbf{Q} & \mathbf{ZA_p} + \mathbf{FM_p} \end{bmatrix},$$

$$\mathbf{\Phi}_{11} = \phi + \phi^\mathbf{T}. \qquad (20)$$

Note that the matrix inequalities (18)–(20) are LMIs in the collection of variables $(\mathbf{L}, \mathbf{F}, \mathbf{Q}, \mathbf{X}, \mathbf{Z}, \mathbf{W^{-1}})$, whereby joint control/sensor/actuator design is a convex problem.

Assume a solution $(\mathbf{L}, \mathbf{F}, \mathbf{Q}, \mathbf{X}, \mathbf{Z}, \mathbf{W})$ is found for the LMIs (18)–(20). Then the problem (17) is solved by the controller

$$\mathbf{G} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ \mathbf{V_l^{-1}} & -\mathbf{V_l^{-1}ZB_p} \end{bmatrix} \begin{bmatrix} \mathbf{Q} - \mathbf{ZA_pX} & \mathbf{F} \\ \mathbf{L} & \mathbf{0} \end{bmatrix} \\ \begin{bmatrix} \mathbf{0} & \mathbf{V_r^{-1}} \\ \mathbf{I} & -\mathbf{M_pXV_r^{-1}} \end{bmatrix}, \qquad (21)$$

where $\mathbf{V_l}$ and $\mathbf{V_r}$ are left and right factors of the matrix $\mathbf{I} - \mathbf{YX}$ (which can be found from the singular value decomposition $\mathbf{I} - \mathbf{YX} = \mathbf{U\Sigma V^T} = (\mathbf{U\Sigma^{1/2}})(\mathbf{\Sigma^{1/2}V^T}) = (\mathbf{V_l})(\mathbf{V_r})$).

To emphasize the theme of this article, to relate optimization to LMIs, we note that three optimization problems present themselves in the above problem with three constraints: control effort $\bar{\mathbf{U}}$, output performance $\bar{\mathbf{Y}}$, and instrument costs $\bar{\$}$. To solve optimization problems, one can fix any two of these prespecified upper bounds and iteratively reduce the level set value of the third "constraint" until feasibility is lost. This process minimizes the resource expressed by the third constraint, while enforcing the other two constraints.

As an example, if cost is not a concern, one can always set large limits for $\bar{\$}$ and discover the best assignment of sensor/actuator precisions for the specified performance requirements. These precisions produced by the algorithm are the values W_{ii}^{-1}, produced from the solution (18)–(20), where the observed rankings $W_{ii}^{-1} > W_{jj}^{-1} > W_{kk}^{-1} > \ldots$ indicate which sensors or actuators are most critical to the required performance goals $(\bar{\mathbf{U}}, \bar{\mathbf{Y}}, \bar{\$})$. If any precision W_{nn}^{-1} is essentially zero, compared to other required precisions, then the math is asserting that the information from this sensor (n) is not important for the control objectives specified, or the control signals through this actuator channel (n) are ineffective in controlling the system to these specifications. This information leads us to a technique for choosing the best sensor actuators and their location.

The previous discussion provides the precisions (W_{ii}^{-1}) required of each sensor and each actuator in the system. Our final application of this theory locates sensors and actuators in a large-scale system, by discarding the least effective ones. Suppose we solve any of the above feasibility problems, by starting with the entire admissible set of sensors and actuators (without regard to cost). For example, in a flexible structure control problem we might not know whether to place a rate sensor or displacement sensors at a given location, so we add both. We might not know whether to use torque or force actuators, so we add both. We fill up the system with all the possibilities we might want to consider, and let the above precision rankings (available after the above LMI problem is solved) reveal how much precision is needed at each location and at each sensor/actuator. If there is a large gap in the precisions required (say $W_{11}^{-1} > W_{22}^{-1} > W_{33}^{-1} >> \ldots W_{nn}^{-1}$), then delete the sensor/actuator n and repeat the LMI problem with one less sensor or actuator. Continue deleting sensors/actuators in

this manner until feasibility of the problem is lost. Then this algorithm, stopping at the previous iteration, has selected the best distribution of sensors/actuators for solving the specific problem specified by the allowable bounds $(\bar{\$}, \bar{U}, \bar{Y})$. The most important contribution of the above algorithm has been to extend control theory to solve system design problems that involve more than just deigning control gains. This enlarges the set of solved linear control problems, from solutions of linear controllers with sensors/actuators prespecified to solutions which specify the sensor/actuator requirements jointly with the control solution.

Summary

LMI techniques provide more powerful tools for designing dynamic linear systems than techniques that minimize a scalar functional for optimization, since multiple goals (bounds) can be achieved for *each* of the outputs and inputs. Optimal control has been a pillar of control theory for the last 50 years. In fact, all of the problems discussed in this article can perhaps be solved by minimizing a scalar functional, but a search is required to find the right functional. Globally convergent algorithms are available to do just that for quadratic functionals. But more direct methods are now available (since the early 1990s) for satisfying multiple constraints. Since then, feasibility approaches have dominated design decisions (at least for linear systems), and such feasibility problems may be convex or not. If the problem can be reduced to a set of LMIs to solve, then convexity is proven. However, failure to find such LMI formulations of the problem does not mean it is not convex, and computer-assisted methods for convex problems are available to avoid the search for LMIs (see Camino et al. 2003). Optimization can also be achieved with LMI methods by reducing the level set for one of the bounds, while maintaining all the other bounds. This level set is reduced iteratively, between convex (LMI) solutions, until feasibility is lost. A most amazing fact is that most of the common linear control design

problems all reduce to exactly the same matrix inequality problem (6). The set of such equivalent problems includes LQR, the set of all stabilizing controllers, the set of all H_∞ controllers, and the set of all L_∞ controllers. The discrete and robust versions of these problems are also included in this equivalent set; 17 control problems have been found to be equivalent to LMI problems.

LMI techniques extend the range of solvable system design problems beyond just control design. By integrating information architecture and control design, one can simultaneously choose the control gains and the precision required of all sensor/actuators to satisfy the closed-loop performance constraints. These techniques can be used to select the information (with precision requirements) required to solve a control or estimation problem, using the best economic solution (minimal precision). Linear Quadratic Optimal Control

Computer Science, University of Groningen,
Groningen, AV, The Netherlands

Abstract

Linear quadratic optimal control is a collective term for a class of optimal control problems involving a linear input-state-output system and a cost functional that is a quadratic form of the state and the input. The aim is to minimize this cost functional over a given class of input functions. The optimal input depends on the initial condition, but can be implemented by means of a state feedback control law independent of the initial condition. Both the feedback gain and the optimal cost can be computed in terms of solutions of Riccati equations.

Keywords

Introduction

Linear quadratic optimal control is a generic term that collects a number of optimal control problems for linear input-state-output systems in which a quadratic cost functional is minimized over a given class of input functions. This functional is formed by integrating a quadratic form of the state and the input over a finite or an infinite time interval. Minimizing the energy of the output over a finite or infinite time interval can be formulated in this framework and in fact provides a major motivation for this class of optimal control problems. A common feature of the solutions to the several versions of the problem is that the optimal input functions can be given in the form of a linear state feedback control law. This makes it possible to implement the optimal controllers as a feedback loop around the system. Another common feature is that the optimal value of the cost functional is a quadratic form of the initial condition on the system. This quadratic form is obtained by taking the appropriate solution of a Riccati differential equation or algebraic Riccati equation associated with the system.

Systems with Inputs and Outputs

Consider the continuous-time, linear time-invariant input-output system in state space form represented by

$$\dot{x}(t) = Ax(t) + Bu(t), \quad z(t) = Cx(t) + Du(t). \tag{1}$$

This system will be referred to as Σ. In (1), A, B, C, and D are maps between suitable spaces (or matrices of suitable dimensions) and the functions x, u, and z are considered to be defined on the real axis $\mathbb{R}$ or on any subinterval of it. In particular, one often assumes the domain of definition to be the nonnegative part of $\mathbb{R}$. The function u is called the *input*, and its values are assumed to be given from outside the system. The class of admissible input functions will be denoted **U**. Often, **U** will be the class of piecewise

continuous or locally integrable functions, but for most purposes, the exact class from which the input functions are chosen is not important. We will assume that input functions take values in an m-dimensional space $\mathcal{U}$, which we often identify with $\mathbb{R}^m$. The variable x is called the *state variable* and it is assumed to take values in an n-dimensional space $\mathcal{X}$. The space $\mathcal{X}$ will be called the *state space*. It will usually be identified with $\mathbb{R}^n$. Finally, z is called the *to be controlled output* of the system and takes values in a p-dimensional space $\mathcal{Z}$, which we identify with $\mathbb{R}^p$. The solution of the differential equation of Σ with initial value $x(0) = x_0$ will be denoted as $x_u(t, x_0)$. It can be given explicitly using the variation-of-constants formula (see Trentelman et al. 2001, p. 38). The set of eigenvalues of a given matrix M is called the *spectrum* of M and is denoted by $\sigma(M)$. The system (1) is called *stabilizable* if there exists a map (matrix of suitable dimensions) F such that $\sigma(A + BF) \subset \mathbb{C}^-$. Here, $\mathbb{C}^-$ denotes the open left half complex plane, i.e., $\{\lambda \in \mathbb{C} \mid \text{Re}(\lambda) < 0\}$. We often express this property by saying that *the pair (A, B) is stabilizable*.

The Linear Quadratic Optimal Control Problem

Assume that our aim is to keep all components of the output $z(t)$ as small as possible, for all $t \geq 0$. In the ideal situation, with initial state $x(0) = 0$, the uncontrolled system (with control input $u = 0$) evolves along the stationary solution $x(t) = 0$. Of course, the output $z(t)$ will then also be equal to zero for all t. If, however, at time $t = 0$ the state of the system is perturbed to, say, $x(0) = x_0$, with $x_0 \neq 0$, then the uncontrolled system will evolve along a state trajectory unequal to the stationary zero solution, and we will get $z(t) = Ce^{At}x_0$. To remedy this, from time $t = 0$ on, we can apply an input function u, so that for $t \geq 0$ the corresponding output becomes equal to $z(t) = Cx_u(t, x_0) + Du(t)$. Keeping in mind that we want the output $z(t)$ to be as small as possible for all $t \geq 0$, we can measure its size by the quadratic cost functional

$$J(x_0, u) = \int_0^\infty \|z(t)\|^2 \, dt, \qquad (2)$$

where $\| \cdot \|$ denotes the Euclidean norm. Our aim to keep the values of the output as small as possible can then be expressed as requiring this integral to be as small as possible by suitable choice of input function u. In this way we arrive at the *linear quadratic optimal control problem*:

Problem 1 Consider the system $\Sigma : \dot{x}(t) = Ax(t) + Bu(t)$, $z(t) = Cx(t) + Du(t)$. Determine for every initial state x_0 an input $u \in \mathbf{U}$ (a space of functions $[0, \infty) \to \mathcal{U}$) such that

$$J(x_0, u) := \int_0^\infty \|z(t)\|^2 \, dt \qquad (3)$$

is minimal. Here $z(t)$ denotes the output trajectory $z_u(t, x_0)$ of Σ corresponding to the initial state x_0 and input function u.

Since the system is linear and the integrand in the cost functional is a quadratic function of z, the problem is called *linear quadratic*. Of course, $\|z\|^2 = x^\top C^\top C x + 2u^\top D^\top C x + u^\top D^\top D u$, so the integrand can also be considered as a quadratic function of (x, u). The convergence of the integral in (3) is of course a point of concern. Therefore, one often considers the corresponding *finite-horizon* problem in a preliminary investigation. In this problem, a final time T is given and one wants to minimize the integral

$$J(x_0, u, T) := \int_0^T \|z(t)\|^2 \, dt. \qquad (4)$$

In contrast to this, the first problem above is sometimes called the *infinite horizon problem*. An important issue is also the *convergence of the state*. Obviously, convergence of the integral does not always imply the convergence to zero of the state. Therefore, distinction is made between the problem with zero and with free endpoint. Problem 1 as stated is referred to as the *problem with free endpoint*. If one restricts the inputs u in the problem to those for which the resulting state trajectory tends to zero, one speaks about the *problem with zero endpoint*. Specifically:

Problem 2 In the situation of Problem 1, determine for every initial state x_0 an input $u \in \mathbf{U}$ such that $x_u(t, x_0) \to 0$ $(t \to \infty)$ and such that under this condition, $J(x_0, u)$ is minimized.

In the literature various special cases of these problems have been considered, and names have been associated to these special cases. In particular, Problems 1 and 2 are called *regular* if the matrix D is injective, equivalently, $D^\top D > 0$. If, in addition, $C^\top D = 0$ and $D^\top D = I$, then the problems are said to be in *standard form*. In the standard case, the integrand in the cost functional reduces to $\|z\|^2 = x^\top C^\top C x + u^\top u$. We often write $Q = C^\top C$. The standard case is a special case, which is not essentially simpler than the general regular problem, but which gives rise to simpler formulas. The general regular problem can be reduced to the standard case by means of a suitable feedback transformation.

The Finite-Horizon Problem

The finite-horizon problem in standard from is formulated as follows:

Problem 3 Given the system $\dot{x}(t) = Ax(t) + Bu(t)$, a final time $T > 0$, and symmetric matrices N and Q such that $N \geq 0$ and $Q \geq 0$, determine for every initial state x_0 a piecewise continuous input function $u : [0, T] \to \mathcal{U}$ such that the integral

$$J(x_0, u, T) := \int_0^T x(t)^\top Q x(t) + u(t)^\top u(t) \, dt$$
$$+ x(T)^\top N x(T) \qquad (5)$$

is minimized.

In this problem, we have introduced a *weight on the final state*, using the matrix N. This generalization of the problem does not give rise to additional complications.

A key ingredient in solving this finite-horizon problem is the *Riccati differential equation* associated with the problem:

$$\dot{P}(t) = A^\top P(t) + P(t)A - P(t)BB^\top P(t) + Q,$$
$$P(0) = N. \qquad (6)$$

This is a quadratic differential equation on the interval $[0, \infty]$ in terms of the matrices A, B, and Q, and with initial condition given by the weight matrix N on the final state. The unknown in the differential equation is the matrix valued function $P(t)$. The following theorem solves the finite-horizon problem. It states that the Riccati differential equation with initial condition (6) has a unique solution on $[0, \infty)$, that the optimal value of the cost functional is determined by the value of this solution at time T, and that there exists a unique optimal input that is generated by a time-varying state feedback control law:

Theorem 1 *Consider Problem 3. The following properties hold:*

1. *The Riccati differential equation with initial value* (6) *has a unique solution $P(t)$ on $[0, \infty)$. This solution is symmetric and positive semidefinite for all $t \geq 0$.*

2. *For each x_0 there is exactly one optimal input function, i.e., a piecewise continuous function u^* on $[0, T]$ such that $J(x_0, u^*, T) = J^*(x_0, T) := \inf\{J(x_0, u, T) \mid u \in \mathbf{U}\}$. This optimal input function u^* is generated by the time-varying feedback control law*

$$u(t) = -B^\top P(T - t)x(t) \quad (0 \leq t \leq T).$$
(7)

3. *For each x_0, the minimal value of the cost functional equals*

$$J^*(x_0, T) = x_0^\top P(T)x_0.$$

4. *If $N = 0$, then the function $t \mapsto P(t)$ is an increasing function in the sense that $P(t) - P(s)$ is positive semidefinite for $t \geq s$.*

The Infinite-Horizon Problem with Free Endpoint

We consider the situation as described in Theorem 1 with $N = 0$. An obvious conjecture is that $x_0^\top P(T)x_0$ converges to the minimal cost of the infinite-horizon problem as $T \to \infty$. The convergence of $x_0^\top P(T)x_0$ for all x_0 is equivalent to the convergence of the matrix $P(T)$ for

$T \to \infty$ to some matrix P^-. Such a convergence does not always take place. In order to achieve convergence, we make the following assumption: for every x_0, there exists an input u for which the integral

$$J(x_0, u) := \int_0^\infty x(t)^\top Q x(t) + u(t)^\top u(t) \, dt$$
(8)

converges, i.e., for which the cost $J(x_0, u)$ is finite. Obviously, for the problem to make sense for all x_0, this condition is necessary. It is easily seen that the stabilizability of (A, B) is a sufficient condition for the above assumption to hold (not necessary, take, e.g., $Q = 0$). Take an arbitrary initial state x_0 and assume that $\bar{u}$ is a function such that the integral (8) is finite. We have for every $T > 0$ that

$$x_0^\top P(T)x_0 \leq J(x_0, \bar{u}, T) \leq J(x_0, \bar{u}),$$

which implies that for every x_0, the expression $x_0^\top P(T)x_0$ is bounded. This implies that $P(T)$ is bounded. Since $P(T)$ is increasing with respect to T, it follows that $P^- := \lim_{T \to \infty} P(T)$ exists. Since P satisfies the differential equation (6), it follows that also $\dot{P}(t)$ has a limit as $t \to \infty$. It is easily seen that this latter limit must be zero. Hence, $P = P^-$ satisfies the following equation:

$$A^\top P + PA - PBB^\top P + Q = 0. \quad (9)$$

This is called the *algebraic Riccati equation* (ARE). The solutions of this equation are exactly the constant solutions of the Riccati differential equation. The previous consideration shows that the ARE has a positive semidefinite solution P^-. The solution is not necessarily unique, not even with the extra condition that $P \geq 0$. However, P^- turns out to be the *smallest* real symmetric positive semidefinite solution of the ARE.

The following theorem now establishes a complete solution to the regular standard form version of Problem 1:

L

Theorem 2 *Consider the system* $\dot{x}(t) = Ax(t) + Bu(t)$ *together with the cost functional*

$$J(x_0, u) := \int_0^\infty x(t)^\top Q x(t) + u(t)^\top u(t)\, dt,$$

with $Q \geq 0$. *Factorize* $Q = C^\top C$. *Then, the following statements are equivalent:*

1. *For every* $x_0 \in \mathcal{X}$, *there exists* $u \in \mathbf{U}$ *such that* $J(x_0, u) < \infty$.
2. *The ARE* (9) *has a real symmetric positive semidefinite solution* P.

Assume that one of the above conditions holds. Then, there exists a smallest real symmetric positive semidefinite solution of the ARE, i.e., there exists a real symmetric solution $P^- \geq 0$ *such that for every real symmetric solution* $P \geq 0$, *we have* $P^- \leq P$. *For every* x_0, *we have*

$$J^*(x_0) := \inf\{J(x_0, u) \mid u \in \mathbf{U}\} = x_0^\top P^- x_0.$$

Furthermore, for every x_0, *there is exactly one optimal input function, i.e., a function* $u^* \in \mathbf{U}$ *such that* $J(x_0, u^*) = J^*(x_0)$. *This optimal input is generated by the time-invariant feedback law*

$$u(t) = -B^\top P^- x(t).$$

The Infinite-Horizon Problem with Zero Endpoint

In addition to the free endpoint problem, we consider the version of the linear quadratic problem with zero endpoint. In this case the aim is to minimize for every x_0 the cost functional over all inputs u such that $x_u(t, x_0) \to 0$ $(t \to \infty)$. For each x_0 such u exists if and only if the pair (A, B) is stabilizable. A solution to the regular standard form version of Problem 2 is stated next:

Theorem 3 *Consider the system* $\dot{x}(t) = Ax(t) + Bu(t)$ *together with the cost functional*

$$J(x_0, u) := \int_0^\infty x(t)^\top Q x(t) + u(t)^\top u(t)\, dt,$$

with $Q \geq 0$. *Assume that* (A, B) *is stabilizable. Then:*

1. *There exists a largest real symmetric solution of the ARE, i.e., there exists a real symmetric solution* P^+ *such that for every real symmetric solution* P, *we have* $P \leq P^+$. P^+ *is positive semidefinite.*
2. *For every initial state* x_0, *we have*

$$J_0^*(x_0) = x_0^\top P^+ x_0.$$

3. *For every initial state* x_0, *there exists an optimal input function, i.e., a function* $u^* \in \mathbf{U}$ *with* $x(\infty) = 0$ *such that* $J(x_0, u^*) = J_0^*(x_0)$ *if and only if every eigenvalue of* A *on the imaginary axis is* (Q, A) *observable, i.e.,*
   $$\mathrm{rank} \begin{pmatrix} A - \lambda I \\ Q \end{pmatrix} = n \text{ for all } \lambda \in \sigma(A) \text{ with}$$
   $\mathrm{Re}(\lambda) = 0$.

   Under this assumption we have:
4. *For every initial state* x_0, *there is exactly one optimal input function* u^*. *This optimal input function is generated by the time-invariant feedback law*

$$u(t) = -B^\top P^+ x(t).$$

5. *The optimal closed-loop system* $\dot{x}(t) = (A - BB^\top P^+)x(t)$ *is stable. In fact,* P^+ *is the unique real symmetric solution of the ARE for which* $\sigma(A - BB^\top P^+) \subset \mathbb{C}^-$.

Summary and Future Directions

Linear quadratic optimal control deals with finding an input function that minimizes a quadratic cost functional for a given linear system. The cost functional is the integral of a quadratic form in the input and state variable of the system. If the integral is taken over, a finite time interval the problem is called a finite-horizon problem, and the optimal cost and optimal state feedback gain can be expressed in terms of the solution of an associated Riccati differential equation. If we integrate over an infinite time interval, the problem is called an infinite-horizon problem. The optimal cost and optimal feedback gain for the free endpoint problem can be found in terms of

the smallest nonnegative real symmetric solution of the associated algebraic Riccati equation. For the zero endpoint problem, these are given in terms of the largest real symmetric solution of the algebraic Riccati equation.

Recommended Reading

The linear quadratic regulator problem and the Riccati equation were introduced by R.E. Kalman in the early 1960s (see Kalman 1960). Extensive treatments of the problem can be found in the textbooks Brockett (1969), Kwakernaak and Sivan (1972), and Anderson and Moore (1971). For a detailed study of the Riccati differential equation and the algebraic Riccati equation, we refer to Wonham (1968). Extensions of the linear quadratic regulator problem to linear quadratic optimization problems, where the integrand of the cost functional is a possibly indefinite quadratic function of the state and input variable, were studied in the classical paper of Willems (1971). A further reference for the geometric classification of all real symmetric solutions of the algebraic Riccati equation is Coppel (1974). For the question what level of system performance can be obtained if, in the cost functional, the weighting matrix of the control input is singular or nearly singular leading to singular and nearly singular linear quadratic optimal control problems and "cheap control" problems, we refer to Kwakernaak and Sivan (1972). An early reference for a discussion on the singular problem is the work of Clements and Anderson (1978). More details can be found in Willems (1971) and Schumacher (1983). In singular problems, in general one allows for distributions as inputs. This approach was

worked out in detail in Hautus and Silverman (1983) and Willems et al. (1986). For a more recent reference, including an extensive list of references, we refer to the textbook of Trentelman et al. (2001).

Linear Quadratic Zero-Sum Two-Person Differential Games

Pierre Bernhard
INRIA-Sophia Antipolis-Méditerranée, Sophia Antipolis, France

Abstract

As in optimal control theory, linear quadratic (LQ) differential games (DG) can be solved, even in high dimension, via a Riccati equation.

However, contrary to the control case, existence of the solution of the Riccati equation is not necessary for the existence of a closed-loop saddle point. One may "survive" a particular, nongeneric, type of conjugate point. An important application of LQDGs is the so-called H_∞-optimal control, appearing in the theory of robust control.

Differential games; Finite horizon; H-infinity control; Infinite horizon

Perfect State Measurement

Linear quadratic differential games are a special case of differential games (DG). See the article ▶ Pursuit-Evasion Games and Zero-Sum Two-Person Differential Games. They were first investigated by Ho et al. (1965), in the context of a linearized pursuit-evasion game. This subsection is based upon Bernhard (1979, 1980). A linear quadratic DG is defined as

$$\dot{x} = Ax + Bu + Dv, \quad x(t_0) = x_0,$$

with $x \in \mathbb{R}^n$, $u \in \mathbb{R}^m$, $v \in \mathbb{R}^\ell$, $u(\cdot) \in L^2([0, T], \mathbb{R}^m)$, $v(\cdot) \in L^2([0, T], \mathbb{R}^\ell)$. Final time T is given, there is no terminal constraint, and using the notation $x^t K x = \|x\|_K^2$,

$$J(t_0, x_0; u(\cdot), v(\cdot)) = \|x(T)\|_K^2 + \int_{t_0}^T (x^t \; u^t \; v^t)$$

$$\begin{pmatrix} Q & S_1 & S_2 \\ S_1^t & R & 0 \\ S_2^t & 0 & -\Gamma \end{pmatrix} \begin{pmatrix} x \\ u \\ v \end{pmatrix} dt.$$

The matrices of appropriate dimensions, A, B, D, Q, S_i, R, and Γ, may all be measurable functions of time. R and Γ must be positive definite with inverses bounded away from zero. To get the most complete results available, we assume also that K and Q are nonnegative definite, although this is only necessary for some of the following results. Detailed results without that assumption were obtained by Zhang (2005) and Delfour (2005). We chose to set the cross term in uv in the criterion null; this is to simplify the results and is not necessary. This problem satisfies Isaacs' condition (see article DG) even with nonzero such cross terms.

Using the change of control variables

$$u = \tilde{u} - R^{-1} S_1^t x, \qquad v = \tilde{v} + \Gamma^{-1} S_2^t x,$$

yields a DG with the same structure, with modified matrices A and Q, but without the cross terms in xu and xv. (This extends to the case with nonzero cross terms in uv.) Thus, without loss of generality, we will proceed with $(S_1 \; S_2) = (0 \; 0)$.

The existence of open-loop and closed-loop solutions to that game is ruled by two Riccati equations for symmetric matrices P and $P^\star$, respectively, and by a pair of canonical equations that we shall see later:

$$\dot{P} + PA + A^t P - PBR^{-1} B^t P + PD\Gamma^{-1} D^t P$$
$$+ Q = 0, P(T) = K, \tag{1}$$

$$\dot{P}^\star + P^\star A + A^t P^\star + P^\star D\Gamma^{-1} D^t P^\star + Q = 0,$$
$$P^\star(T) = K. \tag{2}$$

When both Riccati equations have a solution over $[t, T]$, it holds that in the partial ordering of definiteness,

$$0 \le P(t) \le P^\star(t).$$

When the saddle point exists, it is represented by the state feedback strategies

$$u = \varphi^\star(t, x) = -R^{-1} B^t P(t)x,$$

$$v = \psi^\star(t, x) = \Gamma^{-1} D^t P(t)x. \tag{3}$$

The control functions generated by this pair of feedbacks will be noted $\hat{u}(\cdot)$ and $\tilde{v}(\cdot)$.

Theorem 1
- *A sufficient condition for the existence of a closed-loop saddle point, then given by*

$(\varphi^\star, \psi^\star)$ in (*3*), is that Eq. (*1*) has a solution $P(t)$ defined over $[t_0, T]$.

- *A necessary and sufficient condition for the existence of an open-loop saddle point is that Eq. (*2*) has a solution over $[t_0, T]$ (and then so does (*1*)). In that case, the pairs $(\hat{u}(\cdot), \hat{v}(\cdot))$, $(\hat{u}(\cdot), \psi^\star)$, and $(\varphi^\star, \psi^\star)$ are saddle points.*
- *A necessary and sufficient condition for $(\varphi^\star, \hat{v}(\cdot))$ to be a saddle point is that Eq. (*1*) has a solution over $[t_0, T]$.*
- *In all cases where a saddle point exists, the Value function is $V(t, x) = \|x\|_{P(t)}^2$.*

However, Eq. (*1*) may fail to have a solution and a closed-loop saddle point still exists. The precise necessary condition is as follows: let $X(\cdot)$ and $Y(\cdot)$ be two square matrix function solutions of the *canonical equations*

$$\begin{pmatrix} \dot{X} \\ \dot{Y} \end{pmatrix} = \begin{pmatrix} A & -BR^{-1}B^t + D\Gamma^{-1}D^t \\ -Q & -A^t \end{pmatrix} \begin{pmatrix} X \\ Y \end{pmatrix},$$
$$\begin{pmatrix} X(T) \\ Y(T) \end{pmatrix} = \begin{pmatrix} I \\ K \end{pmatrix}.$$

The matrix $P(t)$ exists for $t \in [t_0, T]$ if and only if $X(t)$ is invertible over that range, and then, $P(t) = Y(t)X^{-1}(t)$. Assume that the rank of $X(t)$ is piecewise constant, and let $X^\dagger(t)$ denote the pseudo-inverse of $X(t)$ and $\mathcal{R}(X(t))$ its range.

Theorem 2 *A necessary and sufficient condition for a closed-loop saddle point to exist, which is then given by (*3*) with $P(t) = Y(t)X^\dagger(t)$, is that*
1. *$x_0 \in \mathcal{R}(X(t_0))$.*
2. *For almost all $t \in [t_0, T]$, $\mathcal{R}(D(t)) \subset \mathcal{R}(X(t))$.*
3. *$\forall t \in [t_0, T]$, $Y(t)X^\dagger(t) \geq 0$.*

In a case where $X(t)$ is only singular at an isolated instant $t^\star$ (then conditions 1 and 2 above are automatically satisfied), called a *conjugate point* but where YX^{-1} remains positive definite on both sides of it, the conjugate point is called *even*. The feedback gain $F = -R^{-1}B^t P$ diverges upon reaching $t^\star$, but on a trajectory generated by this feedback, the control $u(t) =$

$F(t)x(t)$ remains finite. (See an example in Bernhard 1979.)

If $T = \infty$, with all system and payoff matrices constant and $Q > 0$, Mageirou (1976) has shown that if the algebraic Riccati equation obtained by setting $\dot{P} = 0$ in (*1*) admits a positive definite solution P, the game has a Value $\|x\|_P^2$, but (*3*) may not be a saddle point. ($\psi^\star$ may not be an equilibrium strategy.)

H_∞-Optimal Control

This subsection is entirely based upon Başar and Bernhard (1995). It deals with imperfect state measurement, using Bernhard's nonlinear *minimax certainty equivalence principle* (Bernhard and Rapaport 1996).

Several problems of robust control may be brought to the following one: a linear, time-invariant system with two inputs (control input $u \in \mathbb{R}^m$ and disturbance input $w \in \mathbb{R}^\ell$) and two outputs (measured output $y \in \mathbb{R}^p$ and controlled output $z \in \mathbb{R}^q$) is given. One wishes to control the system with a nonanticipative controller $u(\cdot) = \phi(y(\cdot))$ in order to minimize the induced linear operator norm between spaces of square-integrable functions, of the resulting operator $w(\cdot) \mapsto z(\cdot)$.

It turns out that the problem which has a tractable solution is a kind of dual one: given a positive number γ, is it possible to make this norm no larger than γ? The answer to this question is yes if and only if

$$\inf_{\phi \in \Phi} \sup_{w(\cdot) \in L^2} \int_{-\infty}^{\infty} (\|z(t)\|^2 - \gamma^2 \|w(t)\|^2)\, dt \leq 0.$$

We shall extend somewhat this classical problem by allowing either a time variable system, with a finite horizon T, or a time-invariant system with an infinite horizon.

The dynamical system is

$$\dot{x} = Ax + Bu + Dw, \tag{4}$$

$$y = Cx + \qquad Ew, \tag{5}$$

$$z = Hx + Gu. \tag{6}$$

We let

$$\begin{pmatrix} D \\ E \end{pmatrix} (D^t \ E^t) = \begin{pmatrix} M & L \\ L^t & N \end{pmatrix} ,$$

$$\begin{pmatrix} H^t \\ G^t \end{pmatrix} (H \ G) = \begin{pmatrix} Q & S \\ S^t & R \end{pmatrix} ,$$

and we assume that E is onto, $\Leftrightarrow N > 0$, and G is one-to-one $\Leftrightarrow R > 0$.

Finite Horizon

In this part, we consider a time-varying system, with all matrix functions measurable. Since the state is not known exactly, we assume that the initial state is not known either. The issue is therefore to decide whether the criterion

$$J_\gamma = \|x(T)\|_K^2 + \int_{t_0}^{T} (\|z(t)\|^2 - \gamma^2 \|w(t)\|^2)$$

$$\mathrm{d}t - \gamma^2 \|x_0\|_{\Sigma_0}^2 \qquad (7)$$

may be kept finite and with which strategy. Let

$$\gamma^\star = \inf\{\gamma \mid \inf_{\phi \in \Phi} \sup_{x_0 \in \mathbb{R}^n, w(\cdot) \in L^2} J_\gamma < \infty\} .$$

Theorem 3 $\gamma \leq \gamma^\star$ *if and only if the following three conditions are satisfied:*

1. *The following Riccati equation has a solution over* $[t_0, T]$:

$$-\dot{P} = PA + A^t P - (PB + S)R^{-1}(B^t P + S^t)$$

$$+ \gamma^{-2} PMP + Q , \quad P(T) = K . \quad (8)$$

2. *The following Riccati equation has a solution over* $[t_0, T]$:

$$\dot{\Sigma} = A\Sigma + \Sigma A^t - (\Sigma C^t + L)N^{-1}(C\Sigma + L^t)$$

$$+ \gamma^{-2}\Sigma Q \Sigma + M , \quad \Sigma(t_0) = \Sigma_0 . \quad (9)$$

3. *The following spectral radius condition is satisfied:*

$$\forall t \in [t_0, T], \quad \rho(\Sigma(t)P(t)) < \gamma^2 . \quad (10)$$

In that case, the optimal controller ensuring $\inf_\phi \sup_{x_0, w} J_\gamma$ *is given by a "worst case state"* $\hat{x}(\cdot)$ *satisfying* $\hat{x}(0) = 0$ *and*

$$\dot{\hat{x}} = [A - BR^{-1}(B^t P + S^t) + \gamma^{-2}D(D^t P + L^t)]$$

$$\hat{x} + (I - \gamma^{-2}\Sigma P)^{-1}(\Sigma C^t + L)(y - C\hat{x}) , \quad (11)$$

and the certainty equivalent *controller*

$$\phi^\star(y(\cdot))(t) = -R^{-1}(B^t P + S^t)\hat{x}(t) . \quad (12)$$

Infinite Horizon

The infinite horizon case is the traditional H_∞-optimal control problem reformulated in a state space setting. We let all matrices defining the system be constant. We take the integral in (7) from $-\infty$ to $+\infty$, with no initial or terminal term of course. We add the hypothesis that the pairs (A, B) and (A, D) are stabilizable and the pairs (C, A) and (H, A) detectable. Then, the theorem is as follows:

Theorem 4 $\gamma \leq \gamma^\star$ *if and only if the following conditions are satisfied: The algebraic Riccati equations obtained by placing $\dot{P} = 0$ and $\dot{\Sigma} = 0$ in (8) and (9) have positive definite solutions, which satisfy the spectral radius condition (10). The optimal controller is given by Eqs. (11) and (12), where P and Σ are the minimal positive definite solutions of the algebraic Riccati equations, which can be obtained as the limit of the solutions of the differential equations as $t \rightarrow -\infty$ for P and $t \rightarrow \infty$ for Σ.*

Conclusion

The similarity of the H_∞-optimal control theory with the LQG, stochastic, theory is in many respects striking, as is the duality observation control. Yet, the "observer" of H_∞-optimal control does *not* arise from some estimation theory but from the analysis of a "worst case." The best explanation might be in the duality of the ordinary, or $(+, \times)$, algebra with the idempotent $(\max, +)$ algebra (see Bernhard 1996).

The complete theory of H_∞-optimal control in that perspective has yet to be written.

Abstract

Feedback is a fundamental mechanism in nature and central in the control of systems. The state contains important system information, and applying a control law that uses state information is a very powerful control policy. To illustrate the effect of feedback in linear systems, continuous-time and discrete-time state variable descriptions are used: these allow one to write explicitly the resulting closed-loop descriptions and to study the effect of feedback on the eigenvalues of the closed-loop system. The eigenvalue assignment problem is also discussed.

Keywords

Introduction

Feedback is a fundamental mechanism arising in nature. Feedback is also common in engineered systems and is essential in the automatic control of dynamic processes with uncertainties in their model descriptions and in their interactions with the environment. When feedback is used, the actual values of the system variables are sensed, fed back, and used to control the system. That is, a control law decision process is based not only

on predictions on the system behavior derived from a process model (as in open-loop control) but also on information about the actual behavior (closed-loop feedback control).

Linear Continuous-Time Systems

Consider, to begin with, time-invariant systems described by the state variable description

$$\dot{x} = Ax + Bu, \qquad y = Cx + Du, \quad (1)$$

in which $x(t) \in \mathbb{R}^n$ is the state, $u(t) \in \mathbb{R}^m$ is the input, $y(t) \in \mathbb{R}^p$ is the output, and $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $C \in \mathbb{R}^{p \times n}$, $D \in \mathbb{R}^{p \times m}$ are constant matrices. In this case, the linear state feedback (lsf) control law is selected as

$$u(t) = Fx(t) + r(t), \qquad (2)$$

where $F \in \mathbb{R}^{m \times n}$ is the constant gain matrix and $r(t) \in \mathbb{R}^m$ is a new external input.

Substituting (2) into (1) yields the closed-loop state variable description, namely,

$$\begin{aligned}\dot{x} &= (A + BF)x + Br, \\ y &= (C + DF)x + Dr.\end{aligned} \qquad (3)$$

Appropriately selecting F, primarily to modify $A + BF$, one affects and improves the behavior of the system.

A number of comments are in order:

– Feeding back the information from the state x of the system is expected to be, and it is, an effective way to alter the system behavior. This is because knowledge of the (initial) state and the input uniquely determines the system's future behavior and intuitively using the state information should be a good way to control the system, i.e., modifying its behavior.

– In a state feedback control law, the input u can be any function of the state $u = f(x, r)$, not necessarily linear with constant gain F as in (2). Typically given (1) and (2) is selected as the linear state feedback primarily because the resulting closed-loop description (3) is

also a linear time-invariant system. However, depending on the application needs, the state feedback control law (2) can be more complex.

– Although the Eqs. (3) that describe the closed-loop behavior are different from Eq. (1), this does not imply that the system parameters have changed. The way feedback control acts is not by actually changing the system parameters A, B, C, D but by changing u so that closed-loop system behaves as if the parameters were changed. When one applies, say, a step via $r(t)$ in the closed-loop system, then $u(t)$ in (2) is modified appropriately so the system behaves in a desired way.

– It is possible to implement u in (2) as an open-loop control law, namely,

$$\begin{aligned}\hat{u}(s) = {} &F[sI - (A + BF)]^{-1}x(0) \\ &+ [I - F(sI - A)^{-1}B]^{-1}\hat{r}(s) \quad (4)\end{aligned}$$

where Laplace transforms have been used for notational convenience. Equation (4) produces exactly the same input as Eq. (2), but it has the serious disadvantage that it is based exclusively on prior knowledge on the system (notably $x(0)$ and parameters A, B). As a result, when there are uncertainties (and there always are), the open-loop control law (4) may fail, while the closed-loop control law (2) succeeds.

– Analogous definitions exist for continuous-time, time-varying systems described by the equations

$$\dot{x} = A(t)x + B(t)u, \quad y = C(t)x + D(t)u \qquad (5)$$

In this framework, the control law is described by

$$u = F(t)x + r, \qquad (6)$$

and the resulting closed-loop system is

$$\begin{aligned}\dot{x} &= [A(t) + B(t)F(t)]x + B(t)r, \\ y &= [C(t) + D(t)F(t)]x + D(t)r.\end{aligned} \qquad (7)$$

Linear Discrete-Time Systems

For the discrete-time, time-invariant case, the system description is

$$x(k+1) = Ax(k) + Bu(k), \quad y = Cx(k) + Du(k), \tag{8}$$

the linear state feedback control law is defined as

$$u(k) = Fx(k) + r(k), \tag{9}$$

and the closed-loop system is described by

$$\begin{aligned} x(k+1) &= (A + BF)x(k) + Br(k), \\ y(k) &= (C + DF)x(k) + Dr(k). \end{aligned} \tag{10}$$

Similarly, for the discrete-time, time-varying case

$$\begin{aligned} x(k+1) &= A(k)x(k) + B(k)u(k), \\ y(k) &= C(k)x(k) + D(k)u(k), \end{aligned} \tag{11}$$

the control law is defined as

$$u(k) = F(k)x(k) + r(k), \tag{12}$$

and the resulting closed-loop system is

$$\begin{aligned} x(k+1) &= [A(k) + B(k)F(k)]x(k) + B(k)r(k), \\ y(k) &= [C(k) + D(k)F(k)]x(k) + D(k)r(k). \end{aligned} \tag{13}$$

Selecting the Gain F

F (or $F(t)$) is selected so that the closed-loop system has certain desirable properties. Stability is of course of major importance. Many control problems are addressed using linear state feedback including tracking and regulation, diagonal decoupling, and disturbance rejection. Here we shall focus on stability. Stability can be achieved under appropriate controllability assumptions. In the time-varying case, one way to determine such stabilizing $F(t)$ (or $F(k)$) is to use results from the optimal linear quadratic regulator (LQR)

theory which yields the "best" $F(t)$ (or $F(k)$) in some sense.

In the time-invariant case, one can also use a LQR formulation, but here stabilization is equivalent to the problem of assigning the n eigenvalues of $(A + BF)$ in the stable region of the complex plane. If $\lambda_i, i = 1, \ldots, n$, are the eigenvalues of $A + BF$, then F should be chosen so that, for all $i = 1, \ldots, n$, the real part of λ_i, $Re(\lambda_i) < 0$ in the continuous-time case, and the magnitude of λ_i, $|\lambda_i| < 1$ in the discrete-time case. Eigenvalue assignment is therefore an important problem, which is discussed hereafter.

Eigenvalue Assignment Problem

For continuous-time and discrete-time, time-invariant systems, the eigenvalue assignment problem can be posed as follows. Given matrices $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{n \times m}$, find $F \in \mathbb{R}^{m \times n}$ such that the eigenvalues of $A + BF$ are assigned to arbitrary, complex conjugate, locations. Note that the characteristic polynomial of $A + BF$, namely, $\det(sI - (A + BF))$, has real coefficients, which implies that any complex eigenvalue is part of a pair of complex conjugate eigenvalues.

Theorem 1 *The eigenvalue assignment problem has a solution if and only if the pair (A, B) is reachable.*

For single-input systems, that is, for systems with $m = 1$, the eigenvalue assignment problem has a simple solution, as illustrated in the following statement:

Proposition 1 *Consider system (1) or (8). Let $m = 1$. Assume that*

$$rank\ R = n,$$

where

$$R = [B, AB, \ldots A^{n-1}B],$$

that is, the system is reachable. Let $p(s)$ be a desired monic polynomial of degree n. Then there is a (unique) linear state feedback gain matrix F such that the characteristic polynomial of $A + BF$ is equal to $p(s)$. Such linear state feedback gain matrix F is given by

$$F = -\begin{bmatrix} 0 \cdots 0\ 1 \end{bmatrix} R^{-1} p(A). \qquad (14)$$

Proposition 1 provides a constructive way to assign the characteristic polynomial, hence the eigenvalues, of the matrix $A + BF$. Note that, for low order systems, i.e., if $n = 2$ or $n = 3$, it may be convenient to compute directly the characteristic polynomial of $A + BF$ and then compute F using the principle of identity of polynomials, i.e., F should be such that the coefficients of the polynomials $\det(sI - (A + BF))$ and $p(s)$ coincide. Equation (14) is known as Ackermann's formula.

The result summarized in Proposition 1 can be extended to multi-input systems.

Proposition 2 *Consider system (1) or (8). Suppose*

$$rank\ R = n,$$

that is, the system is reachable. Let $p(s)$ be a monic polynomial of degree n. Then there is a linear state feedback gain matrix F such that the characteristic polynomial of $A + BF$ is equal to $p(s)$.

Note that in the case $m > 1$ the linear state feedback gain matrix F assigning the characteristic polynomial of the matrix $A + BF$ is not unique. To compute such a gain matrix, one may exploit the following fact:

Lemma 1 *Consider system (1). Suppose*

$$rank\ R = n,$$

that is, the system is reachable. Let b_i be a nonzero column of the matrix B. Then there is a matrix G such that the single-input system

$$\dot{x} = (A + BG)x + b_i v \qquad (15)$$

is reachable. Similar results are true for discrete-time systems (8).

Exploiting Lemma 1, it is possible to design a matrix F such that the characteristic polynomial of $A + BF$ equals some monic polynomial $p(s)$ of degree n in two steps. First, we compute a matrix G such that the system (15) is reachable, and

then we use Ackermann's formula to compute a linear state feedback gain matrix F such that the characteristic polynomial of

$$A + BG + b_i F$$

is $p(s)$. Note also that if (A, B) is reachable, under mild conditions on A, there exists vector g so that (A, Bg) is reachable.

There are many other methods to assign the eigenvalues which may be found in the references below.

Transfer Functions

If $H_F(s)$ is the transfer function matrix of the closed-loop system (3), it is of interest to find its relation to the open-loop transfer function $H(s)$ of (1). It can be shown that

$$\begin{aligned} H_F(s) &= H(s)[I - F(sI - A)^{-1}B]^{-1} \\ &= H(s)[F(sI - (A + BF))^{-1}B + I] \end{aligned}$$

In the single-input, single-output case, it can be readily shown that the linear state feedback control law (2) only changes the coefficients of the denominator polynomial in the transfer function (this result is also true in the multi-input, multi-output case). Therefore, if any of the (stable) zeros of $H(s)$ need to be changed, the only way to accomplish this via linear state feedback is by pole-zero cancelation (assigning closed-loop poles at the open-loop zero locations; in the MIMO case, closed-loop eigenvalue directions also need to be assigned for cancelations to take place). Note that it is impossible to change the unstable zeros of $H(s)$ under stability, since they would have to be canceled with unstable poles.

Observer-Based Dynamic Controllers

When the state x is not available for feedback, an asymptotic estimator (a Luenberger observer) is typically used to estimate the state. The estimate

$\tilde{x}$ of the state, instead of the actual x, is then used in (2) to control the system, in what is known as the certainty equivalence architecture.

Summary

The notion of state feedback for linear systems has been discussed. It has been shown that state feedback modifies the closed-loop behavior. The related problem of eigenvalue assignment has been discussed, and its connection with the reachability (controllability) properties of the system has been highlighted. The class of feedback laws considered is the simplest possible one. If additional constraints on the input signal, or on the closed-loop performance, are imposed, then one perhaps has to resort to nonlinear state feedback, for example, if the input signal is bounded in amplitude or rate. If constraints such as decoupling of the systems into m noninteracting subsystems or tracking under asymptotic stability are imposed, then dynamic state feedback may be necessary.

Linear Systems: Continuous-Time Impulse Response Descriptions

Panos J. Antsaklis
Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

An important input–output description of a linear continuous-time system is its impulse response, which is the response $h(t, \tau)$ to an impulse applied at time τ. In time-invariant systems that are also causal and at rest at time zero, the impulse response is $h(t, 0)$ and its Laplace transform is the transfer function of the system. Expressions for $h(t, \tau)$ when the system is described by state-variable equations are also derived.

Keywords

Continuous-time; Impulse response descriptions; Linear systems; Time-invariant; Time-varying; Transfer function descriptions

Introduction

Consider linear continuous-time dynamical systems, the input–output behavior of which can be described by an integral representation of the form

$$y(t) = \int_{-\infty}^{+\infty} H(t, \tau)u(\tau)d\tau \qquad (1)$$

where $t, \tau \in \mathbb{R}$, the output is $y(t) \in \mathbb{R}^p$, the input is $u(t) \in \mathbb{R}^m$, and $H : \mathbb{R} \times \mathbb{R} \to \mathbb{R}^{p \times m}$ is assumed to be integrable. For instance, any system in state-variable form

$$\dot{x} = A(t)x + B(t)u$$
$$y = C(t)x + D(t)u \tag{2}$$

or

$$\dot{x} = Ax + Bu$$
$$y = Cx + Du \tag{3}$$

also has a representation of the form (1) as we shall see below.

Note that it is assumed that at $\tau = -\infty$, the system is at rest. $H(t, \tau)$ is the *impulse response matrix* of the system (1). To explain, consider first a single-input single-output system:

$$y(t) = \int_{-\infty}^{+\infty} h(t, \tau)u(\tau)d\tau, \tag{4}$$

and recall that if $\delta(\hat{t}-\tau)$ denotes an impulse (delta or Dirac) function applied at time $\tau = \hat{t}$, then for a function $f(t)$,

$$f(\hat{t}) = \int_{-\infty}^{+\infty} f(\tau)\delta(\hat{t} - \tau)d\tau. \tag{5}$$

If now in (4) $u(\tau) = \delta(\hat{t} - \tau)$, that is, an impulse input is applied at $\tau = \hat{t}$, then the output $y_I(t)$ is

$$y_I(t) = h(t, \hat{t}),$$

i.e., $h(t, \hat{t})$ is the output at time t when an impulse is applied at the input at time $\hat{t}$. So in (4), $h(t, \tau)$ is the response at time t to an impulse applied at time τ. Clearly if the *impulse response $h(t, \tau)$* is known, the response to any input $u(t)$ can be derived via (4), and so $h(t, \tau)$ is an input/output description of the system.

Equation (1) is a generalization of (4) for the multi-input, multi-output case. If we let all the components of $u(\tau)$ in (1) be zero except the jth component, then

$$y_i(t) = \int_{-\infty}^{+\infty} h_{ij}(t, \tau)u_j(\tau)d\tau, \tag{6}$$

$h_{ij}(t, \tau)$ denotes the response of the ith component of the output of system (1) at time t due to an impulse applied to the jth component of the

input at time τ with all remaining components of the input being zero. $H(t, \tau) = [h_{ij}(t, \tau)]$ is called the *impulse response matrix* of the system.

If it is known that system (1) is causal, then the output will be zero before an input is applied. Therefore,

$$H(t, \tau) = 0, \quad \text{for } t < \tau, \tag{7}$$

and (1) becomes

$$y(t) = \int_{-\infty}^{t} H(t, \tau)u(\tau)d\tau. \tag{8}$$

Rewrite (8) as

$$y(t) = \int_{-\infty}^{t_0} H(t, \tau)u(\tau)d\tau + \int_{t_0}^{t} H(t, \tau)u(\tau)d\tau$$

$$= y(t_0) + \int_{t_0}^{t} H(t, \tau)u(\tau)d\tau. \tag{9}$$

If (1) is at rest at $t = t_0$ (i.e., if $u(t) = 0$ for $t \geq t_0$, then $y(t) = 0$ for $t \geq t_0$), $y(t_0) = 0$ and (9) becomes

$$y(t) = \int_{t_0}^{t} H(t, \tau)u(\tau)d\tau. \tag{10}$$

If in addition system (1) is time-invariant, then $H(t, \tau) = H(t - \tau, 0)$ (also written as $H(t - \tau)$) since only the elapsed time $(t - \tau)$ from the application of the impulse is important. Then (10) becomes

$$y(t) = \int_{0}^{t} H(t - \tau)u(\tau)d\tau, \quad t \geq 0, \tag{11}$$

where we chose $t_0 = 0$ without loss of generality. Equation (11) is the description for causal, time-invariant systems, at rest at $t = 0$.

Equation (11) is a convolution integral and if we take the (one-sided or unilateral) Laplace transform of both sides,

$$\hat{y}(s) = \hat{H}(s)\hat{u}(s), \tag{12}$$

where $\hat{y}(s)$, $\hat{u}(s)$ are the Laplace transforms of $y(t)$, $u(t)$ and $\hat{H}(s)$ is the Laplace transform of

the impulse response $H(t)$. $\hat{H}(s)$ is the *transfer function matrix* of the system. Note that the transfer function of a linear, time-invariant system is typically defined as the rational matrix $\hat{H}(s)$ that satisfies (12) for any input and its corresponding output assuming zero initial conditions, which is of course consistent with the above analysis.

Connection to State-Variable Descriptions

When a system is described by the state-variable description (2), then

$$y(t) = \int_{t_0}^{t} [C(t)\Phi(t, \tau)B(\tau) + D(t)\delta(t - \tau)]u(\tau)d\tau, \quad (13)$$

where it was assumed that $x(t_0) = 0$, i.e., the system is at rest at t_0. Here $\Phi(t, \tau)$ is the state transition matrix of the system defined by the Peano-Baker series:

$$\Phi(t, t_0) = I + \int_{t_0}^{t} A(\tau_1)d\tau_1$$
$$+ \int_{t_0}^{t} A(\tau_1) \left[\int_{t_0}^{\tau_1} A(\tau_2)d\tau_2\right] d\tau_1 + \cdots;$$

see ▶ Linear Systems: Continuous-Time, Time–Varying State Variable Descriptions.

Comparing (13) with (10), the impulse response

$$H(t, \tau) = \begin{cases} C(t)\Phi(t, \tau)B(t) + D(t)\delta(t-\tau) & t \geq \tau, \\ 0 & t < \tau. \end{cases} \quad (14)$$

Similarly, when the system is time-invariant and is described by (3),

$$y(t) = \int_{t_0}^{t} [Ce^{A(t-\tau)}B + D\delta(t - \tau)]u(\tau)d\tau, \quad (15)$$

where $x(t_0) = 0$.

Comparing (15) with (11), the impulse response

$$H(t - \tau) = \begin{cases} Ce^{A(t-\tau)}B + D\delta(t - \tau) & t \geq \tau, \\ 0 & t < \tau, \end{cases} \quad (16)$$

or as it is commonly written (taking the time when the impulse is applied to be zero, $\tau = 0$)

$$H(t) = \begin{cases} Ce^{At}B + D\delta(t) & t \geq 0, \\ 0 & t < 0. \end{cases} \quad (17)$$

Take now the (one-sided or unilateral) Laplace transform of both sides in (17) to obtain

$$\hat{H}(s) = C(sI - A)^{-1}B + D, \quad (18)$$

which is the transfer function matrix in terms of the coefficient matrices in the state-variable description (3). Note that (18) can also be derived directly from (3) by assuming zero initial conditions ($x(0) = 0$) and taking Laplace transform of both sides.

Finally, it is easy to show that equivalent state-variable descriptions give rise to the same impulse responses.

Summary

The continuous-time impulse response is an external, input–output description of linear, continuous-time systems. When the system is time-invariant, the Laplace transform of the impulse response $h(t, 0)$ (which is the output response at time t due to an impulse applied at time zero with initial conditions taken to be zero) is the transfer function of the system – another very common input–output description. The relationships with the state-variable descriptions are shown.

LTI Systems

Abstract

Continuous-time processes that can be modeled by linear differential equations with constant coefficients can also be described in a systematic way in terms of state variable descriptions of the form $\dot{x}(t) = Ax(t) + Bu(t)$, $y(t) = Cx(t) + Du(t)$. The response of such systems due to a given input and a set of initial conditions is derived and expressed in terms of the variation of constants formula. Equivalence of state variable descriptions is also discussed.

Keywords

Continuous-time; Linear systems; State variable descriptions; Time-invariant

Introduction

Linear, continuous-time systems are of great interest because they model, exactly or approximately, the behavior over time of many practical physical systems of interest. We are particularly interested in systems, the behavior of which is described by linear, ordinary differential equations with constant coefficients.

Such descriptions can always be rewritten as a set of first-order differential equations, typically in the following convenient state variable form:

$$\dot{x} = Ax(t) + Bu(t), \quad y(t) = Cx(t) + Du(t);$$
$$x(0) = x_0, \tag{1}$$

where $x(t)$, the state vector, is a column vector of dimension n ($x(t) \in \mathbb{R}^n$) and $\dot{x}(t) = \frac{dx}{dt}$ with the derivative being taken element by element. $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $C \in \mathbb{R}^{p \times n}$, $D \in \mathbb{R}^{p \times m}$ are matrices with real entries (these are the constant coefficients that make the system time invariant); and $u(t) \in \mathbb{R}^m$, $y(t) \in \mathbb{R}^p$ are the inputs and outputs of the system. The vector differential equation is the *state equation* and the algebraic equation is the *output equation*.

The advantage of the above state variable description is that for given input $u(t)$ and initial condition $x(0)$, its solution (state and output motions or trajectories) can be conveniently and systematically characterized. This is shown below.

Deriving State Variable Descriptions

Description (1) may be derived directly, by modeling the behavior of a linear, continuous-time, time-invariant system, but more often it is derived either from the linearization of a nonlinear equation around an operating point or a trajectory or from higher-order differential equations that model the system's behavior. The example below illustrates the latter case.
Consider a spring-mass example, where a mass m slides horizontally on a surface with damping coefficient b due to friction and it is attached to a wall by a linear spring of spring constant k. If $y(t)$ denotes the distance of the center of the mass from a position of rest of the spring, by applying Newton's law the following second-order linear ordinary differential equation with constant coefficients is obtained:

$$m\ddot{y}(t) + b\dot{y}(t) + ky(t) = u(t). \qquad (2)$$

Here $\dot{y}(t) = \frac{dy(t)}{dt}$. The motion of the mass $y(t), t > 0$ is uniquely determined if the applied force $u(t), t \geq 0$ is known and at $t = 0$ the initial position $y(0) = y_0$ and initial velocity $\dot{y}(0) = y_1$ are given. To obtain a state variable description, introduce the state variables x_1 and x_2 as

$$x_1(t) = y(t), \quad x_2(t) = \dot{y}(t)$$

to obtain the set of first-order differential equations $m\dot{x}_2(t) + b\dot{x}_2(t) + kx_1(t) = u(t)$ and $\dot{x}(t) = x_2(t)$ which can be rewritten in the form of (1)

$$\begin{bmatrix} \dot{x}_1(t) \\ \dot{x}_2(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\frac{k}{m} & -\frac{b}{m} \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{1}{m} \end{bmatrix} u(t) \qquad (3)$$

and

$$y(t) = \begin{bmatrix} 1 & 0 \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix}$$

with $\begin{bmatrix} x_1(0) \\ x_2(0) \end{bmatrix} = \begin{bmatrix} y_0 \\ y_1 \end{bmatrix}$ as initial conditions. This is of the form (1) where $x(t)$ is a 2-dimensional column vector; A is a 2×2 matrix; B and C are 2-dimensional column and row vectors, respectively; and $x(0) = x_0$.

Notes:

1. It is always possible to obtain a state variable description which is equivalent to a given set of higher-order differential equations

2. The choice of the state variables, here x_1 and x_2, is not unique. Different choices will lead to different A, B, and C.

3. The number of the state variables is typically equal to the order of the set of the higher-order differential equations and equals the number of initial conditions needed to derive the unique solution; in the above example this number is 2.

4. In time-invariant systems, it can be assumed without loss of generality that the starting time is $t = 0$ and so the initial conditions are taken to be $x(0) = x_0$.

Solving $\dot{x} = A(t)x; \; x(0) = x_0$

Consider the homogeneous equation

$$\dot{x} = A(t)x; \quad x(0) = x_0 \qquad (4)$$

where $x(t) = [x_1(t), \ldots, x_n(t)]^T$ is the state vector of dimension n and A is an $n \times n$ matrix with entries real numbers (i.e., $A \in \mathbb{R}^{n \times n}$).

Equation (4) is a special case of (1) where there are no inputs and outputs, u and y. The homogeneous vector differential equation (4) will be solved first, and its solution will be used to find the solution of (1).

Solving (4) is an initial value problem. It can be shown that there always exists a unique solution $\varphi(t)$ such that

$$\dot{\varphi}(t) = A\varphi(t); \quad \varphi(0) = x_0.$$

To find the unique solution, consider first the one-dimensional case, namely,

$$\dot{y}(t) = ay(t); \quad y(0) = y_0$$

the unique solution of which is

$$y(t) = e^{at}y_0, \quad t \geq 0.$$

The scalar exponential e^{at} can be expressed in a series form

$$e^{at} = \sum_{k=0}^{\infty} \frac{t^k}{k!} a^k \left(= 1 + \frac{1}{1}ta + \frac{1}{2}t^2a^2 + \frac{1}{6}t^3a^3 + \dots\right)$$

The generalization to the $n \times n$ matrix exponential (A is $n \times n$) is given by

$$e^{At} = \sum_{k=0}^{\infty} \frac{t^k}{k!} A^k \quad \left(= I_n + At + \frac{1}{2}A^2t^2 + \dots\right) \tag{5}$$

By analogy, let the solution to (4) be

$$(x(t) =)\varphi(t) = e^{At}x_0 \tag{6}$$

It is a solution since if it is substituted into (4),

$$\dot{\varphi}(t) = [A + At + \frac{1}{2}A^2t^2 + \dots]x_0$$
$$= Ae^{At}x_0 = A\varphi(t)$$

and $\varphi(0) = e^{A \cdot 0}x_0 = x_0$, that is, it satisfies the equation and the initial condition. Since the solution of (4) is unique, (6) is the unique solution of (4).

The solution (6) can be derived more formally using the Peano-Baker series (see ▸ Linear Systems: Continuous-Time, Time-Varying State Variable Descriptions), which in the present time-invariant case becomes the defining series for the matrix exponential (5).

System Response

Based on the solution of the homogeneous equation (4), shown in (6), the solution of the state equation in (1) can be shown to be

$$x(t) = e^{At}x_0 + \int_0^t e^{A(t-\tau)}Bu(\tau)d\tau. \tag{7}$$

The following properties for the matrix exponential e^{At} can be shown directly from the defining series:
1. $Ae^{At} = e^{At}A$.
2. $(e^{At})^{-1} = e^{-At}$.

Equation (7) which is known as the *variation of constants formula* can be derived as follows:

Consider $\dot{x} = Ax + Bu$ and let $z(t) = e^{-At}x(t)$. Then $x(t) = e^{At}z(t)$ and substituting

$$Ae^{At}z(t) + e^{At}\dot{z}(t) = Ae^{At}z(t) + Bu(t)$$

or $\dot{z}(t) = e^{-At}Bu(t)$ from which

$$z(t) - z(0) = \int_0^t e^{-A\tau}Bu(\tau)d\tau$$

or

$$e^{-At}x(t) - x(0) = \int_0^t e^{-A\tau}Bu(\tau)d\tau$$

or

$$x(t) = e^{At}x_0 + \int_0^t e^{A(t-\tau)}Bu(\tau)d\tau$$

which is the variation of constants formula (7).

Equation (7) is the sum of two parts, the *state response* (when $u(t) = 0$ and the system is driven only by the initial state conditions) and the *input response* (when $x_0 = 0$ and the system is driven only by the input $u(t)$); this illustrates the linear system principle of superposition.

If the output equation $y(t) = Cx(t) + Du(t)$ is considered, then in view of (7),

$$y(t) = Ce^{At}x_0 + \int_0^t Ce^{A(t-\tau)}Bu(\tau)d\tau + Du(t)$$
$$\tag{8}$$

$$= Ce^{At}x_0 + \int_0^t [Ce^{A(t-\tau)}B$$

$$+ D\delta(t-\tau)]u(\tau)d\tau$$

The second expression involves the Dirac (or impulse or delta) function $\delta(t)$, and it is derived based on the basic property for $\delta(t)$, namely,

$$f(t) = \int_{-\infty}^{\infty} \delta(t-\tau)f(\tau)d\tau$$

It is clear that the matrix exponential e^{At} plays a central role in determining the response of a linear continuous-time, time-invariant system described by (1).

Given A, e^{At} may be determined using several methods including its defining series, diagonalization of A using a similarity transformation (PAP^{-1}), the Cayley-Hamilton theorem, using expressions involving the modes of the system ($e^{At} = \sum_{i=1}^n A_i e^{\lambda_i t}$ when A has n distinct eigenvalues λ_i; $A_i = v_i \tilde{v}_i$ with v_i, $\tilde{v}_i$ the right and left eigenvectors of A that correspond to λ_i ($\tilde{v}_i v_j = 1$, $i = j$ and $\tilde{v}_i v_j = 0$, $i \neq j$)), or using Laplace transform ($e^{At} = \mathcal{L}^{-1}[(sI - A)^{-1}]$). See references below for detailed algorithms.

Equivalent State Variable Descriptions

Given

$$\dot{x} = Ax + Bu, \quad y = Cx + Du \tag{9}$$

consider the new state vector $\tilde{x}$ where

$$\tilde{x} = Px$$

with P a real nonsingular matrix. Substituting $x = P^{-1}\tilde{x}$ in (9), we obtain

$$\dot{\tilde{x}} = \tilde{A}\tilde{x} + \tilde{B}u, \quad y = \tilde{C}\tilde{x} + \tilde{D}u, \tag{10}$$

where

$$\tilde{A} = PAP^{-1}, \ \tilde{B} = PB, \ \tilde{C} = CP^{-1}, \ \tilde{D} = D$$

The state variable descriptions (9) and (10) are called equivalent and P is the equivalence transformation. This transformation corresponds to a change in the basis of the state space, which is a vector space. Appropriately selecting P, one can simplify the structure of $\tilde{A}(= PAP^{-1})$; the matrices $\tilde{A}$ and A are called similar. When the eigenvectors of A are all linearly independent (this is the case, e.g., when all eigenvalues λ_i of A are distinct), then P may be found so that $\tilde{A}$ is diagonal. When e^{At} is to be determined, and $\tilde{A} = PAP^{-1} = \text{diag}[\lambda_i]$ ($\tilde{A}$ and A have the same eigenvalues), then

$$e^{At} = e^{P^{-1}\tilde{A}Pt} = P^{-1}e^{\tilde{A}t}P = P^{-1}\text{diag}[e^{\lambda_i t}]P.$$

Note that it can be easily shown that equivalent state space representations give rise to the same impulse response and transfer function (see ▶ Linear Systems: Continuous-Time Impulse Response Descriptions).

Summary

State variable descriptions for continuous-time time-invariant systems are introduced and the state and output responses to inputs and initial conditions are derived. Equivalence of state variable representations is also discussed.

Recommended Reading

The state variable description of systems received wide acceptance in systems theory beginning in the late 1950s. This was primarily due to the work of R.E. Kalman and others in filtering theory and quadratic control theory and to the work of applied mathematicians concerned with the stability theory of dynamical systems. For comments and extensive references on some of the early contributions in these areas, see Kailath (1980) and Sontag (1990). The use of state variable descriptions in systems and control opened the way for the systematic study of systems with multi-inputs and multi-outputs.

Abstract

Continuous-time processes that can be modeled by linear differential equations with time-varying coefficients can be written in terms of state variable descriptions of the form $\dot{x}(t) = A(t)x(t) + B(t)u(t)$, $y(t) = C(t)x(t) + D(t)u(t)$. The response of such systems due to a given input and initial conditions is derived using the Peano-Baker series. Equivalence of state variable descriptions is also discussed.

Keywords

Introduction

Dynamical processes that can be described or approximated by linear high-order ordinary differential equations with time-varying coefficients can also be described, via a change of variables, by state variable descriptions of the form

$$\dot{x}(t) = A(t)x(t) + B(t)u(t); \quad x(t_0) = x_0$$
$$y(t) = C(t)x(t) + D(t)u(t), \tag{1}$$

where $x(t)$ ($t \in \mathbb{R}$, the set of reals) is a column vector of dimension n ($x(t) \in \mathbb{R}^n$) and $A(t), B(t), C(t), D(t)$ are matrices with entries functions of time t. $A(t) = [a_{ij}(t)]$, $a_{ij}(t) : \mathbb{R} \to \mathbb{R}$. $A(t) \in \mathbb{R}^{n \times n}, B(t) \in \mathbb{R}^{n \times m}, C(t) \in \mathbb{R}^{p \times n}, D(t) \in \mathbb{R}^{p \times m}$. The input vector is $u(t) \in \mathbb{R}^m$ and the output vector is $y(t) \in \mathbb{R}^p$. The vector differential equation in (1) is the *state equation*, while the algebraic equation is the *output equation*.

The advantage of the state variable description (1) is that given an input $u(t)$, $t \geq 0$ and an initial condition $x(t_0) = x_0$, the state trajectory or motion for $t \geq t_0$ can be conveniently characterized. To derive the expressions, we first consider the homogenous state equation and the corresponding initial value problem.

Solving $\dot{x}(t) = A(t)x(t); \; x(t_0) = x_0$

Consider the homogenous equation with the initial condition

$$x(t) = A(t)x(t); \quad x(t_0) = x_0 \qquad (2)$$

where $x(t) = [x_1(t), \ldots, x_n(t)]^T$ is the state (column) vector of dimension n and $A(t)$ is an $n \times n$ matrix with entries functions of time that take on values from the field of reals ($A \in \mathbb{R}^{n \times n}$).

Under certain assumptions on the entries of $A(t)$, a solution of (2) exists and it is unique. These assumptions are satisfied, and a solution exists and is unique in the case, for example, when the entries of $A(t)$ are continuous functions of time. In the following we make this assumption.

To find the unique solution of (2), we use the *method of successive approximations* which when applied to

$$\dot{x}(t) = f(t, x(t)), \quad x(t_0) = x_0 \qquad (3)$$

is described by

$$\phi_0(t) = x_0$$

$$\phi_m(t) = x_0 + \int_{t_0}^{t} f(\tau, \phi_{m-1}(\tau)) d\tau, \quad m = 1, 2, \ldots \qquad (4)$$

As $m \to \infty$, ϕ_m converges to the unique solution of (3), assuming the f satisfies certain conditions.

Applying the method of successive approximations to (2) yields

$$\phi_0(t) = x_0$$

$$\phi_1(t) = x_0 + \int_{t_0}^{t} A(\tau)x_0 d\tau$$

$$\phi_2(t) = x_0 + \int_{t_0}^{t} A(\tau)\phi_1(\tau)x_0 d\tau$$

$$\vdots$$

$$\phi_m(t) = x_0 + \int_{t_0}^{t} A(\tau)\phi_{m-1}(\tau)x_0 d\tau$$

from which

$$\phi_m(t) = \left[I + \int_{t_0}^{t} A(\tau_1) d\tau_1 \right.$$

$$+ \int_{t_0}^{t} A(\tau_1) \int_{t_0}^{\tau_1} A(\tau_2) d\tau_2 d\tau_1 + \ldots$$

$$+ \int_{t_0}^{t} A(\tau_1) \int_{t_0}^{\tau_1} A(\tau_2) \ldots \int_{t_0}^{\tau_{m-1}} A(\tau_m)$$

$$\left. d\tau_m \ldots d\tau_1 \right] x_0$$

When $m \to \infty$, and under the above continuity assumptions on $A(t)$, $\phi_m(t)$ converges to the unique solution of (2), i.e.,

$$\phi(t) = \Phi(t, t_0)x_0 \qquad (5)$$

where

$$\Phi(t, t_0) = I + \int_{t_0}^{t} A(\tau_1) d\tau_1$$

$$+ \int_{t_0}^{t} A(\tau_1) \left[\int_{t_0}^{\tau_1} A(\tau_2) d\tau_2 \right] d\tau_1 + \ldots \qquad (6)$$

Note that $\Phi(t_0, t_0) = I$ and by differentiation it can be seen that

$$\dot{\phi}(t, t_0) = A(t)\phi(t, t_0), \qquad (7)$$

as expected, since (5) is the solution of (2). The $n \times n$ matrix $\Phi(t, t_0)$ is called the *state transition matrix* of (2). The defining series (6) is called the Peano-Baker series.

Note that when $A(t) = A$, a constant matrix, then (6) becomes

$$\Phi(t, t_0) = I + \sum_{k=1}^{\infty} \frac{A^k (t - t_0)^k}{k!} \qquad (8)$$

L

which is the defining series for the matrix exponential $e^{A(t-t_0)}$ (see ► Linear Systems: Continuous-Time, Time-Invariant State Variable Descriptions).

System Response

Based on the solution (5) of $\dot{x} = A(t)x(t)$, the solution of the non-homogenous equation

$$\dot{x}(t) = A(t)x(t) + B(t)u(t); \quad x(t_0) = x_0 \quad (9)$$

can be shown to be

$$\phi(t) = \Phi(t, t_0)x_0 + \int_{t_0}^{t} \Phi(t, \tau)B(\tau)u(\tau)d\tau. \quad (10)$$

Equation (10) is the *variation of constants formula*. This result can be shown via direct substitution of (10) into (9); note that $\phi(t) = \Phi(t_0, t_0)x_0 = x_0$. That (10) is a solution can also be shown using a change of variables in (9), namely,

$$z(t) = \Phi(t_0, t)x(t).$$

Equation (10) is the sum of two parts, the *state response* (when $u(t) = 0$ and the system is driven only by the initial state conditions) and the *input response* (when $x_0 = 0$ and the system is driven only by the input $u(t)$); this illustrates the linear system principle of superposition.

In view of (10), the output $y(t) (= C(t)x(t) + D(t)u(t))$ is

$$y(t) = C(t)\Phi(t, t_0)x_0$$

$$+ \int_{t_0}^{t} C(t)\Phi(t, \tau)B(\tau)u(\tau)d\tau + D(t)u(t)$$

$$= C(t)\Phi(t, t_0)x_0 + \int_{t_0}^{t} [C(t)\Phi(t, \tau)B(\tau)$$

$$+ D(t)\delta(t - \tau)]u(\tau)d\tau$$

The second expression involves the Dirac (or impulse or delta) function $\delta(t)$ and is derived based on the basic property for $\delta(t)$, namely,

$$f(t) = \int_{-\infty}^{+\infty} \delta(t - \tau)f(\tau)d\tau,$$

where $\delta(t - \tau)$ denotes an impulse applied at time $\tau = t$.

Properties of the State Transition Matrix $\Phi(t, t_0)$

In general it is difficult to determine $\Phi(t, t_0)$ explicitly; however, $\Phi(t, t_0)$ may be readily determined in a number of special cases including the cases in which $A(t) = A$, $A(t)$ is diagonal, $A(t)A(\tau) = A(\tau)A(t)$.

Consider $\dot{x} = A(t)x$. We can derive a number of important properties which are described below. It can be shown that given n linearly independent initial conditions x_{0i}, the corresponding n solutions $\phi_i(t)$ are also linearly independent. Let a *fundamental matrix* $\Psi(t)$ of $\dot{x} = A(t)x$ be an $n \times n$ matrix, the columns of which are a set of linearly independent solutions $\phi_1(t), \ldots, \phi_n(t)$. The state transition matrix Φ is the fundamental matrix determined from solutions that correspond to the initial conditions $[1, 0, 0, \ldots]^T$, $[0, 1, 0, \ldots, 0]^T, \ldots [0, 0, \ldots, 1]^T$ (recall that $\Phi(t_0, t_0) = I$). The following are properties of $\Phi(t, t_0)$:

(i) $\Phi(t, t_0) = \Psi(t)\Psi^{-1}(t_0)$ with $\Psi(t)$ any fundamental matrix.

(ii) $\Phi(t, t_0)$ is nonsingular for all t and t_0.

(iii) $\Phi(t, \tau) = \Phi(t, \sigma)\Phi(\sigma, \tau)$ (semigroup property).

(iv) $[\Phi(t, t_0)]^{-1} = \Phi(t_0, t)$.

In the special case of time-invariant systems and $\dot{x} = Ax$, the above properties can be written in terms of the matrix exponential since

$$\Phi(t, t_0) = e^{A(t-t_0)}.$$

Equivalence of State Variable Descriptions

Given the system

$$\dot{x} = A(t)x + B(t)u$$
$$y = C(t)x + D(t)u \tag{11}$$

consider the new state vector $\tilde{x}$

$$\tilde{x}(t) = P(t)x(t)$$

where $P^{-1}(t)$ exists and P and P^{-1} are continuous. Then the system

$$\dot{\tilde{x}} = \tilde{A}(t)\tilde{x} + \tilde{B}(t)u$$
$$y = \tilde{C}(t)\tilde{x} + \tilde{D}(t)u$$

where

$$\tilde{A}(t) = [P(t)A(t) + \dot{P}(t)]P^{-1}(t)$$
$$\tilde{B}(t) = P(t)B(t)$$
$$\tilde{C}(t) = C(t)P^{-1}(t)$$
$$\tilde{D}(t) = D(t)$$

is equivalent to (1). It can be easily shown that equivalent descriptions give rise to the same impulse responses.

Summary

State variable descriptions for continuous-time time-varying systems were introduced and the state and output responses to inputs and initial conditions were derived. The equivalence of state variable representations was also discussed.

Linear Systems: Discrete-Time Impulse Response Descriptions

Panos J. Antsaklis
Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

An important input-output description of a linear discrete-time system is its (discrete-time) impulse response (or pulse response), which is the response $h(k, k_0)$ to a discrete impulse applied at time k_0. In time-invariant systems that are also causal and at rest at time zero, the impulse response is $h(k, 0)$, and its z-transform is the transfer function of the system. Expressions for $h(k, k_0)$ when the system is described by state variable equations are derived.

Keywords

At rest; Causal; Discrete-time; Discrete-time impulse response descriptions; Linear systems; Pulse response descriptions; Time-invariant; Time-varying; Transfer function descriptions

Introduction

Consider linear, discrete-time dynamical systems that can be described by

$$y(k) = \sum_{l=-\infty}^{+\infty} H(k,l)u(l) \tag{1}$$

where $k, l \in \mathbb{Z}$ is the set of integers, the output is $y(k) \in \mathbb{R}^p$, the input is $u(k) \in \mathbb{R}^m$, and $H(k,l) : \mathbb{Z} \times \mathbb{Z} \to \mathbb{R}^{p \times m}$. For instance, any system that can be written in state variable form

$$\begin{aligned} x(k+1) &= A(k)x(k) + B(k)u(k) \\ y(k) &= C(k)x(k) + D(k)u(k) \end{aligned} \tag{2}$$

or

$$\begin{aligned} x(k+1) &= Ax(k) + Bu(k) \\ y(k) &= Cx(k) + Du(k) \end{aligned} \tag{3}$$

can be represented by (1). Note that it is assumed that at $l = -\infty$, the system is at rest, i.e., no energy is stored in the system at time $-\infty$.

Define the discrete-time impulse (or unit pulse) as

$$\delta(k) = \begin{cases} 1 & k = 0 \\ 0 & k \neq 0 \end{cases}, k \in \mathbb{Z}$$

and consider a single-input, single-output system:

$$y(k) = \sum_{l=-\infty}^{+\infty} h(k,l)u(l) \tag{4}$$

If $u(l) = \delta(\hat{l} - l)$, that is, the input is a unit pulse applied at $l = \hat{l}$, then the output is

$$y_I(k) = h(k, \hat{l}),$$

i.e., $h(k, \hat{l})$ is the output at time k when a unit pulse is applied at time $\hat{l}$.

So in (4) $h(k, l)$ is the response at time k to a discrete-time impulse (unit pulse) applied at time l. $h(k, l)$ is the *discrete-time impulse response* of the system. Clearly if $h(k, l)$ is known, the response of the system to any input can be determined via (4). So $h(k, l)$ is an input/output description of the system.

Equation (1) is a generalization of (4) for the multi-input, multi-output case. If we let all the components of $u(l)$ in (1) be zero except for the jth component, then

$$y_i(k) = \sum_{l=-\infty}^{+\infty} h_{ij}(k,l)u_j(l) \tag{5}$$

$h_{ij}(k, l)$ denotes the response of the ith component of the output of system (1) at time k due to a discrete impulse applied to the jth component of the input at time l with all remaining components of the input being zero. $H(k, l) = [h_{ij}(k, l)]$ is called the *impulse response matrix* of the system.

If it is known that system (1) is *causal*, then the output will be zero before an input is applied. Therefore,

$$H(k, l) = 0, \quad \text{for } k < l, \tag{6}$$

and so when causality is present, (1) becomes

$$y(k) = \sum_{l=-\infty}^{k} H(k,l)u(l). \tag{7}$$

A system described by (1) is at rest at $k = k_0$ if $u(k) = 0$ for $k \geqslant k_0$ implies $y(k) = 0$ for $k \geqslant k_0$. For a system at rest at $k = k_0$, (7) becomes

$$y(k) = \sum_{l=k_0}^{k} H(k,l)u(l). \tag{8}$$

If system (1) is time-invariant, then $H(k, l) = H(k - l, 0)$ (also written as $H(k - l)$) since only the time elapsed $(k - l)$ from the application of the discrete-time impulse is important. Then (8) becomes

$$y(k) = \sum_{l=0}^{k} H(k-l)u(l), \quad k \geq 0, \quad (9)$$

where we chose $k_0 = 0$ without loss of generality. Equation (9) is the description for casual, time-invariant systems, at rest at $k = 0$.

Equation (9) is a convolution sum and if we take the (one-sided or unilateral) z-transform of both sides,

$$\hat{y}(z) = \hat{H}(z)\hat{u}(z), \quad (10)$$

where $\hat{y}(z)$, $\hat{u}(z)$ are the z-transforms of $y(k)$, $u(k)$ and $\hat{H}(z)$ is the z-transform of the discrete-time impulse response $H(k)$. $\hat{H}(z)$ is the *transfer function matrix* of the system. Note that the transfer function of a linear, time-invariant system is defined as the rational matrix $\hat{H}(z)$ that satisfies (10) for any input and its corresponding output assuming zero initial conditions.

Connections to State Variable Descriptions

When a system is described by (2), then

$$y(k) = \sum_{l=k_0}^{k-1} C(k)\Phi(k, l+1)B(l)u(l)$$
$$+ D(k)u(k), \quad k > k_0 \quad (11)$$

where it was assumed that $x(k_0) = 0$, i.e., the system is at rest at k_0. Here $\Phi(k, l) (= A(k-1)\cdots A(l))$ is the state transition matrix of the system.

Comparing (11) with (8), the discrete-time impulse response of the system is

$$H(k, l) = \begin{cases} C(k)\Phi(k, l+1)B(l) & k > l \\ D(k) & k = l \\ 0 & k < l \end{cases} \quad (12)$$

Similarly, when the system is time-invariant and is described by (3),

$$y(k) = \sum_{l=k_0}^{k-1} C A^{k-(l+1)} Bu(l) + Du(k), \quad k > k_0 \quad (13)$$

where $x(k_0) = 0$ and

$$H(k, l) = H(k-l) = \begin{cases} C A^{k-(l+1)} B & k > l \\ D & k = l \\ 0 & k < l \end{cases} \quad (14)$$

When $l = 0$ (taking the time when the discrete impulse is applied to be zero, $l = 0$), the discrete-time impulse response is

$$H(k) = \begin{cases} C A^{k-1} B & k > 0 \\ D & k = 0 \\ 0 & k < 0 \end{cases} \quad (15)$$

Taking (one-sided or unilateral) z-transforms of both sides in (15),

$$\hat{H}(z) = C(zI - A)^{-1}B + D \quad (16)$$

which is the transfer function matrix in terms of the coefficient matrices in the state variable description (3). Note that (16) can also be derived directly from (3) by assuming zero initial conditions ($x(0) = 0$) and taking z-transforms of both sides.

Finally, it is easy to show that equivalent state variable descriptions give rise to the same discrete-impulse response.

Summary

The discrete-time impulse response is an external, input-output description of linear, discrete-time systems. When the system is time-invariant, the z-transform of the impulse response $h(k, 0)$ (which is the output response at time k due to a discrete impulse applied at time zero with initial conditions taken to be zero) is the transfer function – another very common input-output description. The relationships to the state variable descriptions were shown.

Cross-References

Recommended Reading

External or input-output descriptions such as the impulse response and the transfer function (in the time-invariant case) are described in several textbooks below.

Linear Systems: Discrete-Time, Time-Invariant State Variable Descriptions

Panos J. Antsaklis
Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

Discrete-time processes that can be modeled by linear difference equations with constant coefficients can also be described in a systematic way in terms of state variable descriptions of the form $x(k + 1) = Ax(k) + Bu(k)$, $y(k) = Cx(k) + Du(k)$. The response of such systems due to a given input and subject to initial conditions is derived. Equivalence of state variable descriptions is also discussed.

Keywords

Introduction

Discrete-time systems arise in a variety of ways in the modeling process. There are systems that are inherently defined only at discrete points in time; examples include digital devices, inventory systems, economic systems such as banking where interest is calculated and added to savings accounts at discrete time interval, etc. There are also systems that describe continuous-time systems at discrete points in time; examples include simulations of continuous processes using digital computers and feedback control systems that employ digital controllers and give rise to sampled-data systems.

Linear, discrete-time, time-invariant systems can be modeled via state variable equations, namely,

$$x(k + 1) = Ax(k) + Bu(k); \quad x(0) = x_0$$
$$y(k) = Cx(k) + Du(k)$$

$$(1)$$

where $k \in \mathbb{Z}$, the set of integers, the state vector $x \in \mathbb{R}^n$, i.e., an n dimensional column vector; $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $C \in \mathbb{R}^{p \times n}$, $D \in \mathbb{R}^{p \times m}$ are matrices with entries of real numbers; and $y(k) \in \mathbb{R}^p$, $u(k) \in \mathbb{R}^m$ the output and the input, respectively. The vector difference equation in (1) is the *state equation* and the algebraic equation is the *output equation*.

Note that (1) could have been equivalently written as $x(l) = Ax(l - 1) + Bu(l - 1)$ where $l = k + 1$ and $x(l - 1)$ is an easily visualized delayed version of $x(l)$; this is a form more common in signal processing (where a two-sided or bilateral z-transform is used). In control where we assume a known initial condition at time equal to zero (and one-sided or unilateral z-transform is taken), the form in (1) is common.

Similar to the continuous-time case, (1) can be derived from a set of high-order difference equations by introducing the state variables

$x(k) = [x_1(k), \ldots, x_n(k)]^T$. Description (1) can also be derived from continuous-time system descriptions by sampling (see ▶ Sampled-Data Systems).

The advantage of the above state variable description is that given any input $u(k)$ and initial conditions $x(0)$, its solution (state trajectory or motion) can be conveniently and systematically characterized. This is done below. We first consider the solutions of the homogenous equation $x(k + 1) = Ax(k)$.

Solving $x(k + 1) = Ax(k)$; $x(0) = x_0$

Consider the homogenous equation

$$x(k + 1) = Ax(k); \quad x(0) = x_0 \qquad (2)$$

where $k \in \mathbb{Z}^+$ is a nonnegative integer, $x(k) = [x_1(k), \ldots, x_n(k)]^T$ is the state column vectors of dimension n, and A is an $n \times n$ matrix with entries real numbers (i.e., $A \in \mathbb{R}^{n \times n}$).

Write (2) for $k = 0, 1, 2, \ldots$, namely, $x(1) = Ax(0)$, $x(2) = Ax(1) = A^2x(0), \ldots$ to derive the solution

$$x(k) = A^k x(0), \quad k \geq 0 \qquad (3)$$

This result can be shown formally by induction. Note that $A^0 = I$ by convention and so (3) also satisfies the initial condition.

If the initial time were some (integer) k_0 instead of zero, then the solution would be

$$x(k) = A^{k-k_0} x(k_0), \quad k \geq k_0 \qquad (4)$$

The solution can be written as

$$x(k) = \Phi(k, k_0) x(k_0)$$
$$= \Phi(k - k_0, 0) x(k_0), \quad k \geq k_0 \qquad (5)$$

where $\Phi(k, k_0)$ is the state transition matrix and it equals $\Phi(k, k_0) = A^{k-k_0}$. Note that for time-invariant systems, the initial time k_0 can always be taken to be zero without loss of generality; this is because the behavior depends only on the

time elapsed $(k - k_0)$ and not on the actual initial time k_0.

In view of (3), it is clear that A^k plays an important role in the solutions of the difference state equations that describe linear, discrete-time, time-invariant systems; it is actually analogous to the role e^{At} plays in the solutions of the linear differential state equations that describe linear, continuous-time, time-invariant systems.

Notice that in (3), $k \geq 0$. This is so because A^k for $k < 0$ may not exist; this is the case, for example, when A is a singular matrix – it has at least one eigenvalue at the origin. In contrast, e^{At} exists for any t positive or negative. The implication is that in discrete-time systems we may not be able to determine uniquely the initial past state $x(0)$ from a current state value $x(k)$; in contrast, in continuous-time systems, it is always possible to go backwards in time.

There are several methods to calculate A^k that mirror the methods to calculate e^{At}. One could, for example, use similarity transformations, or the z-transform. When all eigenvectors of A are linearly independent (this is the case, e.g., when all eigenvalues λ_i of A are distinct), then a similarity transformation exists so that

$$PAP^{-1} = \tilde{A} = \text{diag}[\lambda_i].$$

Then

$$A^k = P^{-1}\tilde{A}^k P = P^{-1} \begin{bmatrix} \lambda_1^k & & \\ & \ddots & \\ & & \lambda_n^k \end{bmatrix} P.$$

Alternatively, using the z-transforms, $A^k = \mathcal{Z}^{-1}\{z(zI - A)^{-1}\}$. Also when the eigenvalues λ_i of A are distinct, then

$$A^k = \sum_{i=0}^{n} A_i \lambda_i^k,$$

where $A_i = v_i \tilde{v}_i$ with $v_i, \tilde{v}_i$ the right and left eigenvectors of A that correspond to λ_i. Note that

$$\begin{bmatrix} \tilde{v}_1 \\ \vdots \\ \tilde{v}_n \end{bmatrix} = \begin{bmatrix} v_1 \cdots v_n \end{bmatrix}^{-1},$$

$A_i \lambda_i^k$ are the modes of the system. One could also use the Cayley-Hamilton theorem to determine A^k.

System Response

Consider the description (1). The response can be easily derived by writing the equation for $k = 0, 1, 2, \ldots$ and substituting or formally by induction. It is

$$x(k) = A^k x(0) + \sum_{j=0}^{k-1} A^{k-(j+1)} Bu(j), \quad k > 0 \tag{6}$$

and

$$y(k) = C A^k x(0) + \sum_{j=0}^{k-1} C A^{k-(j+1)} Bu(j)$$
$$+ Du(k), \quad k > 0$$
$$y(0) = Cx(0) + Du(0). \tag{7}$$

Note that (6) can also be written as

$$x(k) = A^k x(0) + [B, AB, \cdots, A^{k-1}B] \begin{bmatrix} u(k-1) \\ \vdots \\ u(0) \end{bmatrix}. \tag{8}$$

Clearly the response is the sum of two components, one due to the initial condition (state response) and one due to the input (input response). This illustrates the linear system principle of superposition.

If the initial time is k_0 and (4) is used, then

$$y(k) = C A^{k-k_0} x(k_0) + \sum_{j=k_0}^{k-1} C A^{k-(j+1)} Bu(j)$$
$$+ Du(k), k > k_0$$
$$y(k_0) = Cx(k_0) + Du(k_0). \tag{9}$$

Equivalence of State Variable Descriptions

Given description (1), consider the new state vector $\tilde{x}$ where

$$\tilde{x}(k) = P x(k)$$

with $P \in \mathbb{R}^{n \times n}$ a real nonsingular matrix.

Substituting $x = P^{-1}\tilde{x}$ in (1), we obtain

$$\tilde{x}(k+1) = \tilde{A}\tilde{x}(k) + \tilde{B}u(k)$$
$$y(k) = \tilde{C}\tilde{x}(k) + \tilde{D}u(k) \tag{10}$$

where

$$\tilde{A} = PAP^{-1}, \ \tilde{B} = PB, \ \tilde{C} = CP^{-1}, \ \tilde{D} = D$$

The state variable descriptions (1) and (9) are called equivalent and P is the equivalence transformation matrix. This transformation corresponds to a change in the basis of the state space, which is a vector space. Appropriately selecting P one can simplify the structure of $\tilde{A}$ (= PAP^{-1}). It can be easily shown that equivalent description gives rise to the same discrete impulse response and transfer function.

Summary

State variable descriptions for discrete-time, time-invariant systems were introduced and the state and output responses to inputs and initial conditions were derived. The equivalence of state variable representations was also discussed.

Cross-References

Recommended Reading

The state variable descriptions received wide acceptance in systems theory beginning in the late 1950s. This was primarily due to the work of R.E. Kalman. For historical comments and extensive references, see Kailath (1980). The use of state variable descriptions in systems and control opened the way for the systematic study of systems with multi-inputs and multi-outputs.

Linear Systems: Discrete-Time, Time-Varying, State Variable Descriptions

Panos J. Antsaklis
Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Abstract

Discrete-time processes that can be modeled by linear difference equations with time-varying coefficients can be written in terms of state variable descriptions of the form $x(k+1) = A(k)x(k) + B(k)u(k)$, $y(k) = C(k)x(k) + D(k)u(k)$. The response of such systems due to a given input and initial conditions is derived. Equivalence of state variable descriptions is also discussed.

Keywords

Discrete-time; Linear systems; State variable descriptions; Time-varying

Introduction

Discrete-time systems arise in a variety of ways in the modeling process. There are systems that are inherently defined only at discrete points in time; examples include digital devices, inventory systems, and economic systems such as banking where interest is calculated and added to savings accounts at discrete time interval. There are also systems that describe continuous-time systems at discrete points in time; examples include simulations of continuous processes using digital computers and feedback control systems that employ digital controllers and give rise to sampled-data systems.

Dynamical processes that can be described or approximated by linear difference equations with time-varying coefficients can also be described, via a change of variables, by state variable descriptions of the form

$$x(k+1) = A(k)x(k) + B(k)u(k); \ x(k_0) = x_0$$
$$y(k) = C(k)x(k) + D(k)u(k).$$

(1)

Above, the state vector $x(k)$ ($k \in \mathbb{Z}$, the set of integers) is a column vector of dimension n ($x(k) \in \mathbb{R}^n$); the output is $y(k) \in \mathbb{R}^m$ and the input is $u(k) \in \mathbb{R}^m$. $A(k)$, $B(k)$, $C(k)$, and $D(k)$ are matrices with entries functions of time k, $A(k) = [a_{ij}(k)]$, $a_{ij}(k) : \mathbb{Z} \to \mathbb{R}$ ($A(k) \in \mathbb{R}^{n \times n}$, $B(k) \in \mathbb{R}^{n \times m}$, $C(k) \in \mathbb{R}^{p \times n}$, $D(k) \in \mathbb{R}^{p \times m}$). The vector difference equation in (1) is the state equation, while the algebraic equation is the output equation. Note that in the time-invariant case, $A(k) = A$, $B(k) = B$, $C(k) = C$, and $D(k) = D$.

The advantage of the state variable description (1) is that given an input $u(k)$, $k \geq k_0$ and an initial condition $x(k_0) = x_0$, the state trajectories or motions for $k \geq k_0$ can be conveniently characterized. To determine the expressions, we first consider the homogeneous state equation and the corresponding initial value problem.

Solving $x(k+1) = A(k)x(k)$; $x(k_0) = x_0$

Consider the homogenous equation

L

$$x(k + 1) = A(k)x(k); \quad x(k_0) = x_0 \quad (2)$$

Note that

$$x(k_0 + 1) = A(k_0)x(k_0)$$

$$x(k_0 + 2) = A(k_0 + 1)A(k_0)x(k_0)$$

$$\vdots$$

$$x(k) = A(k - 1)A(k - 2)\cdots A(k_0)x(k_0)$$

$$= \prod_{j=k_0}^{k-1} A(j)x(k_0), \quad k > k_0$$

This result can be shown formally by induction. The solution of (2) is then

$$x(k) = \Phi(k, k_0)x(k_0), \quad (3)$$

where $\Phi(k, k_0)$ is the *state transition matrix* of (2) given by

$$\Phi(k, k_0) = \prod_{j=k_0}^{k-1} A(j), \quad k > k_0; \ \ \Phi(k_0, k_0) = I.$$

$$(4)$$

Note that in the time-invariant case, $\Phi(k, k_0) = A^{k-k_0}$.

System Response

Consider now the state equation in (1). It can be easily shown that the solution is

$$x(k) = \Phi(k, k_0)x(k_0)$$

$$+ \sum_{j=k_0}^{k-1} \Phi(k, j + 1)B(j)u(j), \quad k > k_0,$$

$$(5)$$

and the response $y(k)$ of (1) is

$$y(k) = C(k)\Phi(k, k_0)x(k_0)$$

$$+ C(k) \sum_{j=k_0}^{k-1} \Phi(k, j + 1)B(j)u(j)$$

$$+ D(k)u(k), \quad k > k_0, \quad (6)$$

and

$$y(k_0) = C(k_0)x(k_0) + D(k_0)u(k_0).$$

Equation (5) is the sum of two parts, the *state response* (when $u(k) = 0$ and the system is driven only by the initial state conditions) and the *input response* (when $x(k_0) = 0$ and the system is driven only by the input $u(k)$); this illustrates the linear systems principle of superposition.

Equivalence of State Variable Descriptions

Given (1), consider the new state vector $\tilde{x}$ where

$$\tilde{x}(k) = P(k)x(k)$$

where $P^{-1}(k)$ exists. Then

$$\tilde{x}(k + 1) = \tilde{A}(k)\tilde{x}(k) + \tilde{B}(k)u(k)$$

$$y(k) = \tilde{C}(k)\tilde{x}(k) + \tilde{D}(k)u(k)$$

$$(7)$$

where

$$\tilde{A}(k) = P(k + 1)A(k)P^{-1}(k),$$

$$\tilde{B}(k) = P(k + 1)B(k),$$

$$\tilde{C}(k) = C(k)P^{-1}(k),$$

$$\tilde{D}(k) = D(k)$$

is equivalent to (1). It can be easily shown that equivalent descriptions give rise to the same discrete impulse responses.

Summary

State variable descriptions for linear discrete-time time-varying systems were introduced and the state and output responses to inputs and initial conditions were derived. The equivalence of state variable representations was also discussed.

LMI Approach to Robust Control

Kang-Zhi Liu
Department of Electrical and Electronic Engineering, Chiba University, Chiba, Japan

Abstract

In the analysis and design of robust control systems, LMI method plays a fundamental role. This article gives a brief introduction to this topic. After the introduction of LMI, it is illustrated how a control design problem is related with matrix inequality. Then, two methods are explained on how to transform a control problem characterized by matrix inequalities to LMIs, which is the core of the LMI approach. Based on this knowledge, the LMI solutions to various kinds of robust control problems are illustrated. Included are $\mathcal{H}_\infty$ and $\mathcal{H}_2$ control, regional pole placement, and gain-scheduled control.

Keywords

Introduction of LMI

A matrix inequality in a form of

$$F(x) = F_0 + \sum_{i=1}^{m} x_i F_i > 0 \qquad (1)$$

is called an LMI (linear matrix inequality). Here, $x = [x_1 \cdots x_m]$ is the unknown vector and $F_i (i = 1, \ldots, m)$ is a symmetric matrix. $F(x)$ is an affine function of x. The inequality means that $F(x)$ is positive definite.

LMI can be solved effectively by numerical algorithms such as the famous interior point method (Nesterov and Nemirovskii 1994). MATLAB has an LMI toolbox (Gahinet et al. 1995) tailored for solving the related control problems. Boyd et al. (1994) provide detailed theoretic fundamentals of LMI. A comprehensive and up-to-date treatment on the applications of LMI in robust control is covered in Liu and Yao (2014).

The notation $\text{He}(A) = A + A^T$ is used to simplify the presentation of large matrices; $A_\perp$ is a matrix whose columns form the basis of the kernel space of A, i.e., $AA_\perp = 0$. Further, $A \otimes B$ denotes the Kronecker product of matrices (A, B).

L

Control Problems and LMI

In control problems, it is often the case that the variables are matrices. For example, the necessary and sufficient condition for the stability of a linear system $\dot{x}(t) = Ax(t)$ is that there exists a positive-definite matrix P satisfying the inequality $AP + PA^T < 0$. Although this is different from the LMI of Eq. (1) in form, it can be converted to Eq. (1) equivalently by using a basis of symmetric matrices.

Next, consider the stabilization of system $\dot{x} = Ax + Bu$ by a state feedback $u = Fx$. The closed-loop system is $\dot{x} = (A + BF)x$. Therefore, the stability condition is that there exist a positive-definite matrix P and a feedback gain matrix F satisfying the inequality

$$(A + BF)P + P(A + BF)^T < 0. \quad (2)$$

In this inequality, FP, the product of unknown variables F and P, appears. Such matrix inequality is called a *bilinear matrix inequality*, or *BMI* for short. BMI problem is non-convex and difficult to solve. There are mainly two methods for transforming a BMI into an LMI: variable elimination and variable change.

From BMI to LMI: Variable Elimination

The method of variable elimination is good at optimizing single-objective problems. This method is based on the theorem below (Gahinet and Apkarian 1994).

Lemma 1 *Given real matrices E, F, G with G being symmetric, the inequality*

$$E^T X F + F^T X^T E + G < 0 \quad (3)$$

has a solution X if and only if the following two inequalities hold simultaneously

$$E_\perp^T G E_\perp < 0, \quad F_\perp^T G F_\perp < 0. \quad (4)$$

Application of this theorem to the previous stabilization problem (2) yields $(B^T)_\perp^T (AP + PA^T)(B^T)_\perp < 0$, which is an LMI about P. Once P is obtained, it may be substituted back into the inequality (2) and solve for F.

For output feedback problems, it is often needed to construct a new matrix from two given matrices in solving a control problem with LMI approach. The method is given by the following lemma.

Lemma 2 *Given two n-dimensional positive-definite matrices X and Y, a 2n-dimensional positive-definite matrix $\mathbb{P}$ satisfying the conditions*

$$\mathbb{P} = \begin{bmatrix} Y & * \\ * & * \end{bmatrix}, \quad \mathbb{P}^{-1} = \begin{bmatrix} X & * \\ * & * \end{bmatrix}$$

can be constructed if and only if

$$\begin{bmatrix} X & I \\ I & Y \end{bmatrix} > 0. \quad (5)$$

Factorizing $Y - X^{-1}$ as FF^T, a solution is given by

$$\mathbb{P} = \begin{bmatrix} Y & F \\ F^T & I \end{bmatrix}.$$

As an example of output feedback control design, let us consider the stabilization of the plant

$$\dot{x}_P = Ax_P + Bu, \ y = Cx_P \quad (6)$$

with a full-order dynamic controller

$$\dot{x}_K = A_K x_K + B_K y, \ u = C_K x_K + D_K y. \quad (7)$$

The closed-loop system is

$$\begin{bmatrix} \dot{x}_P \\ \dot{x}_K \end{bmatrix} = A_c \begin{bmatrix} x_P \\ x_K \end{bmatrix}, A_c = \begin{bmatrix} A + BD_K C & BC_K \\ B_K C & A_K \end{bmatrix}. \quad (8)$$

The stability condition is that the matrix inequality

$$A_c^T \mathbb{P} + \mathbb{P} A_c < 0 \quad (9)$$

has a solution $\mathbb{P} > 0$. To apply the variable elimination method, we need to put all coefficient matrices of the controller into in a single matrix. This is done as follows:

$$A_c = \overline{A} + \overline{B}\mathcal{K}\overline{C}, \ \mathcal{K} = \begin{bmatrix} D_K & C_K \\ B_K & A_K \end{bmatrix} \quad (10)$$

in which $\overline{A} = \text{diag}(A, 0)$, $\overline{B} = \text{diag}(B, I)$, and $\overline{C} = \text{diag}(C, I)$, all being block diagonal. Then, based on Lemma 1, the stability condition reduces to the existence of symmetric matrices X, Y satisfying LMIs

$$(B^T)_{\perp}^T (AX + XA^T)(B^T)_{\perp} < 0 \quad (11)$$

$$(C_{\perp})^T (YA + A^T Y)C_{\perp} < 0. \quad (12)$$

Meanwhile, the positive definiteness of matrix $\mathbb{P}$ is guaranteed by Eq. (5) in Lemma 2.

From BMI to LMI: Variable Change

We may also use the method of variable change to transform a BMI into an LMI. This method is good at multi-objective optimization.

The detail is as follows (Gahinet 1996). A positive-definite matrix can always be factorized as the quotient of two triangular matrices, i.e.,

$$\mathbb{P}\Pi_1 = \Pi_2, \Pi_1 = \begin{bmatrix} X & I \\ M^T & 0 \end{bmatrix}, \Pi_2 = \begin{bmatrix} I & Y \\ 0 & N^T \end{bmatrix}. \quad (13)$$

$\mathbb{P} > 0$ is guaranteed by Eq. (5) for a full-order controller. Further, the matrices M, N are computed from $MN^T = I - XY$. Consequently, they are nonsingular.
An equivalent inequality $\Pi_1^T A_c^T \Pi_2 + \Pi_2^T A_c \Pi_1 < 0$ is obtained by multiplying Eq. (9) with Π_1^T and Π_1. After a change of variables, this inequality reduces to an LMI

$$\text{He} \begin{bmatrix} AX + B\mathbb{C} & A + B\mathbb{D}C + \mathbb{A}^T \\ 0 & YA + \mathbb{B}C \end{bmatrix} < 0. \quad (14)$$

The new variables $\mathbb{A}, \mathbb{B}, \mathbb{C}, \mathbb{D}$ are set as

LMI Approach to Robust Control, Fig. 1 Generalized feedback system

$$\begin{aligned} \mathbb{A} &= NA_K M^T + NB_K CX + YBC_K M^T \\ &\quad + Y(A + BD_K C)X \\ \mathbb{B} &= NB_K + YBD_K, \quad \mathbb{C} = C_K M^T \\ &\quad + D_K CX, \quad \mathbb{D} = D_K. \end{aligned} \quad (15)$$

The coefficient matrices of the controller become

$$\begin{aligned} D_K &= \mathbb{D}, C_K = (\mathbb{C} - D_K CX)M^{-T}, \\ B_K &= N^{-1}(\mathbb{B} - YBD_K) \\ A_K &= N^{-1}(\mathbb{A} - NB_K CX - YBC_K M^T \\ &\quad - Y(A + BD_K C)X)M^{-T}. \end{aligned} \quad (16)$$

$\mathcal{H}_2$ and $\mathcal{H}_\infty$ Control

In system optimization, $\mathcal{H}_2$ and $\mathcal{H}_\infty$ norms are the most popular and effective performance indices. $\mathcal{H}_2$ norm of a transfer function is closely related with the squared area of its impulse response. So, a smaller $\mathcal{H}_2$ norm implies a faster response. Meanwhile, $\mathcal{H}_\infty$ norm of a transfer function is the largest magnitude of its frequency response. Hence, for a transfer function from the disturbance to the controlled output, a smaller $\mathcal{H}_\infty$ norm guarantees a better disturbance attenuation.

Usually $\mathcal{H}_2$ and $\mathcal{H}_\infty$ optimization problems are treated in the generalized feedback system of Fig. 1. Here, the generalized plant $G(s)$ includes the nominal plant, the performance index, and the weighting functions.

Let the generalized plant $G(s)$ be

$$G(s) = \begin{bmatrix} C_1 \\ C_2 \end{bmatrix} (sI - A)^{-1} \begin{bmatrix} B_1 & B_2 \end{bmatrix} + \begin{bmatrix} D_{11} & D_{12} \\ D_{21} & 0 \end{bmatrix}. \quad (17)$$

Further, the stabilizability of (A, B_2) and the detectability of (C_2, A) are assumed. The

closed-loop transfer matrix from the disturbance w to the performance output z is denoted by

$$H_{zw}(s) = C_c(sI - A_c)^{-1}B_c + D_c. \qquad (18)$$

The condition for $H_{zw}(s)$ to have an $\mathcal{H}_2$ norm less than γ, i.e., $\|H_{zw}\|_2 < \gamma$, is that there are symmetric matrices $\mathbb{P}$ and W satisfying

$$\begin{bmatrix} \mathbb{P}A_c + A_c^T\mathbb{P} & C_c^T \\ C_c & -I \end{bmatrix} < 0, \quad \begin{bmatrix} W & B_c^T\mathbb{P} \\ \mathbb{P}B_c & \mathbb{P} \end{bmatrix} > 0 \qquad (19)$$

as well as $\mathrm{Tr}(W) < \gamma^2$. Here, $\mathrm{Tr}(W)$ denotes the trace of matrix W, i.e., the sum of its diagonal entries.

The LMI solution is derived via the application of the variable change method, as given below.

Theorem 1 *Suppose that $D_{11} = 0$. The $\mathcal{H}_2$ control problem is solvable if and only if there exist symmetric matrices X, Y, W and matrices $\mathbb{A}$, $\mathbb{B}$, $\mathbb{C}$ satisfying the following LMIs:*

$$\mathrm{He}\begin{bmatrix} AX + B_2\mathbb{C} & 0 & 0 \\ A^T + \mathbb{A} & YA + \mathbb{B}C_2 & 0 \\ C_1X + D_{12}\mathbb{C} & C_1 & -\frac{1}{2}I \end{bmatrix} < 0 \qquad (20)$$

$$\begin{bmatrix} W & B_1^T & B_1^TY \\ B_1 & X & I \\ YB_1 & I & Y \end{bmatrix} > 0, \ \mathrm{Tr}(W) < \gamma^2. \qquad (21)$$

When the LMI Eqs. (20) *and* (21) *have solutions, an $\mathcal{H}_2$ controller is given by* Eq. (16) *by setting* $\mathbb{D} = 0$.

The $\mathcal{H}_\infty$ control problem is to design a controller so that $\|H_{zw}\|_\infty < \gamma$. The starting point of $\mathcal{H}_\infty$ control is the famous bounded real lemma, which states that $H_{zw}(s)$ has an $\mathcal{H}_\infty$ norm less than γ if and only if there is a positive-definite matrix $\mathbb{P}$ satisfying

$$\begin{bmatrix} A_c^T\mathbb{P} + \mathbb{P}A_c & \mathbb{P}B_c & C_c^T \\ B_c^T\mathbb{P} & -\gamma I & D_c^T \\ C_c & D_c & -\gamma I \end{bmatrix} < 0. \qquad (22)$$

There are two kinds of LMI solutions to this control problem: one based on variable elimination and one based on variable change.

To state the first solution, define the following matrices first:

$$N_Y = [C_2 \ D_{21}]_\perp, \ \ N_X = [B_2^T \ D_{12}^T]_\perp. \qquad (23)$$

Theorem 2 *The $\mathcal{H}_\infty$ control problem has a solution if and only if* Eq. (5) *and the following LMIs have positive-definite solutions X, Y:*

$$\begin{bmatrix} N_X^T & 0 \\ 0 & I \end{bmatrix}\begin{bmatrix} AX + XA^T & XC_1^T & B_1 \\ C_1X & -\gamma I & D_{11} \\ B_1^T & D_{11}^T & -\gamma I \end{bmatrix}$$
$$\times \begin{bmatrix} N_X & 0 \\ 0 & I \end{bmatrix} < 0 \qquad (24)$$

$$\begin{bmatrix} N_Y^T & 0 \\ 0 & I \end{bmatrix}\begin{bmatrix} YA + A^TY & YB_1 & C_1^T \\ B_1^TY & -\gamma I & D_{11}^T \\ C_1 & D_{11} & -\gamma I \end{bmatrix}$$
$$\times \begin{bmatrix} N_Y & 0 \\ 0 & I \end{bmatrix} < 0. \qquad (25)$$

Once a matrix $\mathbb{P}$ is computed according to Lemma 2, Eq. (22) becomes an LMI and its solution yields the controller.

The second solution is given below.

Theorem 3 *The $\mathcal{H}_\infty$ control problem has a solution if and only if* Eq. (5) *and the following LMI have solutions X, Y and $\mathbb{A}$, $\mathbb{B}$, $\mathbb{C}$, $\mathbb{D}$:*

$$\mathrm{He}\begin{bmatrix} AX + B_2\mathbb{C} & A + B_2\mathbb{D}C_2 & B_1 + B_2\mathbb{D}D_{21} & 0 \\ \mathbb{A} & YA + \mathbb{B}C_2 & YB_1 + \mathbb{B}D_{21} & 0 \\ 0 & 0 & -\frac{\gamma}{2}I & 0 \\ C_1X + D_{12}\mathbb{C} & C_1 + D_{12}\mathbb{D}C_2 & D_{11} + D_{12}\mathbb{D}D_{21} & -\frac{\gamma}{2}I \end{bmatrix} < 0. \qquad (26)$$

The controller is given by Eq. (16).

Regional Pole Placement

The location of system poles determines the response quality. However, for uncertain systems it is impossible to place the closed-loop poles at fixed points because they move with the variation of the plant. Nevertheless, it is still possible to place the closed-loop poles inside a region. For convex regions characterized by LMI, the design method is mature and proven effective in practice.

Let us see how to characterize a convex region. It is easy to know that a complex number z is inside the disk of Fig. 2a if and only if it satisfies

$$\begin{bmatrix} -r & z+c \\ \bar{z}+c & -r \end{bmatrix} < 0.$$

Similarly, z is inside the sector of Fig. 2b if and only if

$$\begin{bmatrix} (z+\bar{z})\sin\theta & (z-\bar{z})\cos\theta \\ -(z-\bar{z})\cos\theta & (z+\bar{z})\sin\theta \end{bmatrix} < 0.$$

Generally, the set of complex number z characterized by

$$D = \{z \in \mathbb{C} | L + zM + \bar{z}M^T < 0\} \qquad (27)$$

is called an LMI region, in which L is a symmetric matrix. For the dynamic system

$$\dot{x} = Ax, \qquad (28)$$

all of its poles are in the LMI region D if and only if there is a positive-definite matrix $\mathbb{P}$ satisfying the LMI

$$L \otimes \mathbb{P} + M \otimes (A\mathbb{P}) + M^T \otimes (A\mathbb{P})^T < 0. \quad (29)$$

This forms the basis for the regional pole placement design.

For the disk region in Fig. 2a, the condition becomes

$$\begin{bmatrix} -r\mathbb{P} & c\mathbb{P}+A\mathbb{P} \\ c\mathbb{P}+(A\mathbb{P})^T & -r\mathbb{P} \end{bmatrix} < 0. \qquad (30)$$

Meanwhile, for the sector region in Fig. 2b, the corresponding LMI is

$$\begin{bmatrix} (A\mathbb{P}+\mathbb{P}A^T)\sin\theta & (A\mathbb{P}-\mathbb{P}A^T)\cos\theta \\ -(A\mathbb{P}-\mathbb{P}A^T)\cos\theta & (A\mathbb{P}+\mathbb{P}A^T)\sin\theta \end{bmatrix} < 0. \tag{31}$$

Moreover, for a composite LMI region, such as the intersection of the disk and the sector, the pole placement is guaranteed by enforcing a common solution $\mathbb{P}$ to all the corresponding LMIs.

In the pole placement design, only the variable change method is applicable. For example, in the nominal closed-loop system Eq. (8), the pole placement condition is that the LMI

$$L \otimes \begin{bmatrix} X & I \\ I & Y \end{bmatrix}$$
$$+ \text{He}\left(M \otimes \begin{bmatrix} AX+B\mathbb{C} & A+B\mathbb{D}C \\ \mathbb{A} & YA+\mathbb{B}C \end{bmatrix} \right) < 0 \tag{32}$$

and Eq. (5) are solvable (Chilali and Gahinet 1996).

For systems with norm-bounded parameter uncertainty, a robust pole placement method is provided in Chilali et al. (1999).

Multi-objective Control

It is noted that all of the preceding control designs involve a positive-definite matrix $\mathbb{P}$. Therefore, a multi-objective control design is easily realized

LMI Approach to Robust Control, Fig. 2 Typical examples of LMI region

L

by enforcing a common solution $\mathbb{P}$ to the corresponding matrix inequality conditions.

Gain-Scheduled Control

In practice, many nonlinear systems can be expressed as linear systems with state-dependent coefficients in form, which is known as the LPV (linear parameter-varying) form. For example, in the model of a robot arm $J\ddot{\theta} + mgl\sin\theta = u$, if we define a parameter as $p(t) = \sin\theta/\theta$, then it can be written as an LPV model $J\ddot{\theta}(t) + mglp(t)\theta(t) = u(t)$. In this class of systems, when the parameter $p(t)$ is available online and its range is finite, one may tune the controller parameters based on the information of $p(t)$, so as to achieve a higher performance. This is referred to as gain-scheduled control.

Consider the following affine model:

$$\dot{x} = A(p(t))x + B_1(p(t))d + B_2(p(t))u \quad (33)$$

$$z = C_1(p(t))x + D_{11}d + D_{12}u \quad (34)$$

$$y = C_2(p(t))x + D_{21}d \quad (35)$$

where $A(p) \sim C_2(p)$ are affine functions of the time-varying parameter vector $p(t)$, such as $A(p) = A_0 + \sum_{i=1}^{q} p_i(t)A_i$. The gain-scheduled control is to impose, on the coefficient matrices of the controller, the same affine structure about $p(t)$ such as $A_K(p) = A_{K0} + \sum_{i=1}^{q} p_i(t)A_{Ki}$.

To simplify the design, it is desirable that the coefficient matrices of the closed-loop system become affine functions of the parameter vector $p(t)$. This may be satisfied by restraining some of the matrices of the controller to constant ones. The easy-to-design structure of a gain-scheduled controller is summarized as follows:

- Both $B_2(p)$ and $C_2(p)$ depend on $p(t)$: (B_K, C_K) must be constant matrices besides $D_K = 0$.
- Constant (B_2, C_2): All coefficient matrices of the controller can be affine functions of the parameter vector $p(t)$.
- Constant B_2: (B_K, D_K) must be constant matrices.
- Constant C_2: (C_K, D_K) must be constant matrices.

When the structure of the gain-scheduled controller is chosen as summarized above, the solvability conditions reduce to those at all vertices θ_i of the scheduling parameter vector $p(t)$. Further, a multi-objective is achieved by imposing a common solution $\mathbb{P}$ to all LMI conditions. Some concrete examples are illustrated below:

$\mathcal{H}_\infty$ *Norm Spec*: The conditions of Theorem 3 are satisfied at all vertices θ_j of the parameter vector $p(t)$.

$\mathcal{H}_2$ *Norm Spec*: The conditions of Theorem 1 are satisfied at all vertices θ_j of the parameter vector $p(t)$.

Regional Pole Placement: Eq. (32) is satisfied at all vertices θ_j of the parameter vector $p(t)$ and Eq. (5) holds.

Moreover, a different gain-scheduled method is proposed in Packard (1994) for parametric systems with norm-bounded uncertainty.

Summary and Future Direction

LMI approach is a very powerful method that can be applied to solve most of the robust control problems smartly and effectively. In particular, its capability of handling the multi-objective control problems is very attractive and proven useful in industrial applications.

Further study is needed in the following directions.

- New method of variable change is desired in order to deal with the robust performance design of parametric systems.
- Almost all robust performance designs are carried out based on sufficient conditions. It is very important to discover less conservative design methods.

Lyapunov Methods in Power System Stability

Hsiao-Dong Chiang
School of Electrical and Computer Engineering, Cornell University, Ithaca, NY, USA

Abstract

Energy functions, an extension of Lyapunov functions, have been used in electric power systems for several applications. An overview of energy function theory for general nonlinear autonomous dynamical systems along with its applications to electric power systems is presented. The issue of how to optimally determine the critical level value of an energy function for estimating stability regions of nonlinear dynamical systems is also addressed.

Keywords

Introduction

Energy functions, an extension of the Lyapunov functions, have been practically used in electric power systems for several applications. A comprehensive energy function theory for general nonlinear autonomous dynamical systems along with its applications to electric power systems will be summarized in this article.

We consider a general nonlinear autonomous dynamical system described by the following equation:

$$\dot{x}(t) = f(x(t)) \tag{1}$$

We say a function $V : R^n \to R$ is an energy function for the system (1) if the following three conditions are satisfied (Chiang et al. 1987):

(E1): The derivative of the energy function $V(x)$ along any system trajectory $x(t)$ is nonpositive, i.e., $\dot{V}(x(t)) \leq 0$.

(E2): If $x(t)$ is a nontrivial trajectory (i.e., $x(t)$ is not an equilibrium point), then along the nontrivial trajectory $x(t)$ the set $\{t \in R : \dot{V}(x(t)) = 0\}$ has measure zero in R.

(E3): That a trajectory $x(t)$ has a bounded value of $V(x(t))$ for $t \in R^+$ implies that the trajectory $x(t)$ is also bounded.

Condition (E1) indicates that the value of an energy function is nonincreasing along its trajectory, but does not imply that the energy function is strictly decreasing along any trajectory. Conditions (E1) and (E2) imply that the energy function is strictly decreasing along any system trajectory. Property (E3) states that the energy function is a proper map along any system trajectory but need not be a proper map for the entire state space. Obviously, an energy function may not be a Lyapunov function.

As an illustration of the energy function, we consider the following classical transient stability model and derive an energy function for the model. Consider a power system consisting of n generators. Let the loads be modeled as constant impedances. Under the assumption that the transfer conductance of the reduced network after eliminating all load buses is zero, the dynamics of the ith generator can be represented by the equations

$$\dot{\delta}_i = \omega_i$$

$$M_i \dot{\omega}_i = P_i - D_i \omega_i - \sum_{j=1} V_i V_j B_{ij} \sin(\delta_i - \delta_j)$$

$$(2)$$

where the voltage at node $i+1$ is served as the reference, i.e., $\delta_{i+1} := 0$. This is a version of the so-called *classical model* of the power system. It can be shown that the following function is an energy function $V(\delta, \omega)$ which satisfies conditions (E1)–(E3) for the classical model (2).

$$V(\delta, \omega) = \frac{1}{2} \sum_{i=1}^{n} M_i \omega_i^{\mathbf{2}} - \sum_{i=1}^{n} P_i \left(\delta_i - \delta_j^s \right)$$
$$- \sum_{i=1}^{n} \sum_{j=i+1}^{n+1} V_i V_j B_{ij} \mathbf{cos}(\delta_i - \delta_j)$$
$$- \mathbf{cos}(\delta_i^s - \delta_j^s) \qquad (3)$$

where $x^s = (\delta^s, \mathbf{0})$ is the stable equilibrium point under consideration.

Energy Function Theory

In general, the dynamical behaviors of trajectories of general nonlinear systems can be very complicated. The asymptotical behaviors (i.e., the ω-limit set) of trajectories can be quasiperiodic trajectories or chaotic trajectories. However, as shown below, every trajectory of system (1) having an energy function has only two modes of behaviors: its trajectory either converges to an equilibrium point or goes to infinity (becomes unbounded) as time increases. This result is explained in the following theorem:

Theorem 1 (Global Behavior of Trajectories) *If there exists a function satisfying condition (E1) and condition (E2) of the energy function for system (1), then every bounded trajectory of system (1) converges to one of the equilibrium points.*

Theorem 1 asserts that there does not exist any limit cycle (oscillatory behavior) or bounded complicated behavior such as almost periodic trajectory, chaotic motion, etc. in the system. We next show a sharper result, asserting that every trajectory on the stability boundary must converge to one of the unstable equilibrium points (UEPs) on the stability boundary. Recall that for a hyperbolic equilibrium point, it is an *(asymptotically) stable equilibrium point* if all the eigenvalues of its corresponding Jacobian have negative real parts; otherwise it is an *unstable equilibrium point*. Let $\hat{x}$ be a hyperbolic equilibrium point. Its stable and unstable manifolds, $W^s(\hat{x})$ and $W^u(\hat{x})$, are well defined. There are many physical systems such as electric power systems containing multiple stable equilibrium points. A useful concept for these kinds of systems is that of the *stability region* (also called the *region of attraction*). The stability region of a stable equilibrium point x_s is defined as

$$A(x_s) := \left\{ x \in R^n : \lim_{t \to \infty} \mathbf{\Phi}_t(x) = x_s \right\}$$

The boundary of stability region $A(x_s)$ is called the *stability boundary* of (x_s) and will be denoted by $\partial A(x_s)$.

Theorem 2 (Trajectories on the Stability Boundary (Chiang et al. 1987)) *If there exists an energy function for system (1), then every trajectory on the stability boundary $\partial A(x_s)$ converges to one of the equilibrium points on the stability boundary $\partial A(x_s)$.*

The significance of this theorem is that it offers an effective way to characterize the stability boundary. In fact, Theorem 2 asserts that the stability boundary $\partial A(x_s)$ is contained in the union of stable manifolds of the UEPs on the stability boundary, i.e.,

$$\partial A(x_s) \subseteq \bigcup_{x_i \in \{E \cap \partial A(x_s)\}} W^s(x_i)$$

The following two theorems give interesting results on the structure of the equilibrium points on the stability boundary. Moreover, it presents a necessary condition for the existence of certain types of equilibrium points on a *bounded* stability boundary.

Theorem 3 (Structure of Equilibrium Points on the Stability Boundary (Chiang and Thorp 1989)) *If there exists an energy function for system (1) which has an asymptotically stable equilibrium point x_s (but not globally asymptotically stable), then the stability boundary (x_s) must contain at least one type one equilibrium point. If, furthermore, the stability region is bounded, then the stability boundary $\partial A(x_s)$ must contain at least one type one equilibrium point and one source.*

Theorem 4 (Sufficient Condition for Unbounded Stability Region (Chiang et al. 1987)) *If there exists an energy function for system (1) which has an asymptotically stable equilibrium point x_s (but not globally asymptotically stable) and if $\partial A(x_s)$ contains no source, then the stability region $A(x_s)$ is unbounded.*

A direct application of this is that the stability boundary $\partial A(x_s)$ of an (asymptotically) stable equilibrium point of the classical power system stability model (2) is unbounded.

Optimally Estimating Stability Region Using Energy Functions

In this section, we focus on how to optimally determine the critical level value of an energy function for estimating the stability boundary $\partial A(x_s)$. We consider the following set:

$$S_v(k) = \{x \in R^n : V(x) < k\} \qquad (4)$$

where $V(.) : R^n \rightarrow R$ is an energy function. We shall call the boundary of set (2) $\partial S(k) := \{x \in R^n : V(x) = k\}$ the *level set* (or *constant energy surface*) and k the *level value*. Generally speaking, this set $S(k)$ can be very complicated with several connected components even for the 2-dimensional case. We use the notation $S_k(x_s)$ to denote the only component of the several disjoint connected components of S_k that contains the stable equilibrium point x_s.

Theorem 5 (Optimal Estimation) *Consider the nonlinear system (1) which has an energy function $V(x)$. Let x_s be an asymptotically stable equilibrium point whose stability region $A(x_s)$ is not dense in R^n. Let E_1 be the set of type one equilibrium points and $\hat{c} = \min_{x_i \in \partial A(x_s) \cap_1^E} V(x_i)$, and then*
1. *$S_{\hat{c}}(x_s) \subset A(x_s)$.*
2. *The set $\{S_b(x_s) \cap \bar{A}^c(x_s)\}$ is nonempty for any number $b > c$.*

This theorem leads to an optimal estimation of the stability region $A(x_s)$ via an energy function $V(.)$ (Chiang and Thorp 1989). For the purpose of illustration, we consider the following simple example:

$$\dot{x}_1 = -\sin x_i - 0.5 \sin(x_1 - x_2) + 0.01$$
$$\dot{x}_2 = -0.5 \sin x_2 - 0.5 \sin(x_2 - x_1) + 0.05 \quad (5)$$

It is easy to show that the following function is an energy function for system (5):

$$V(x_1, x_2) = -2\cos x_1 - \cos x_2 - \cos(x_1 - x_2)$$
$$-0.02x_1 - 0.1x_2 \qquad (6)$$

The point $x^s \left(x_1^s, x_2^s\right) = (0.02801, 0.06403)$ is the stable equilibrium point whose stability region is to be estimated. Applying the optimal scheme to system (5), we have the critical level value of -0.31329. The Curve A in Fig. 1 is the exact stability boundary $\partial A(x^s)$ while Curve B is the stability boundary estimated by the connected component (containing the s.e.p. x^s) of the constant energy surface. It can be seen that the critical level value, -0.31329, is indeed the optimal value.
Lyapunov Methods in Power System Stability, Fig. 1

(5), while Curve B is the stability boundary estimated by
the constant energy surface (with level value of -0.31329)
of the energy function

Constructing Analytical Energy Functions for Transient Stability Models

The task of constructing an energy function for
a (post-fault) transient stability model is essential
to direct stability analysis of power systems. The
role of the energy function is to make feasible
a direct determination of whether a given point
(such as the initial point of a post-fault power sys-
tem) lies inside the stability region of post-fault
SEP without performing numerical integration. It
has been shown that a general (analytical) energy
function for power systems with losses does not
exist (Chiang 1989). One key implication is that
any general procedure attempting to construct
an energy function for a lossy power system
transient stability model must include a step that
checks for the existence of an energy function.
This step essentially plays the same role as the
Lyapunov equation in determining the stability of
an equilibrium point.

Several schemes are available for constructing
numerical energy functions for power system
transient stability models expressed as a set of
general differential-algebraic equations (DAEs)
(Chu and Chiang 1999, 2005).

Applications

After decades of research and development in
the energy-function-based direct methods and the
time-domain simulation approach, it has become
clear that the capabilities of direct methods and
that of the time-domain approach complement
each other. The current direction of development
is to include appropriate direct methods and time-
domain simulation programs within the body of
overall power system stability simulation pro-
grams (Chiang 1999, 2011; Chiang et al. 1995;
Fouad and Vittal 1991; Sauer and Pai 1998).
For example, the direct method provides the ad-
vantages of fast computational speed and energy
margins which make it a good complement to
the traditional time-domain approach. The en-
ergy margin and its functional relations to cer-
tain power system parameters are an effective
complement to develop tools such as preventive
control schemes for credible contingencies which
are unstable and to develop fast calculators for
available transfer capability limited by transient
stability.

An effective, theory-based methodology for
online screening and ranking of a large set
of contingencies at operating points obtained
from state estimators has been developed in
Chiang et al. (2013). A set of improved BCU
classifiers, along with their analytical basis,
has been developed. Extensive evaluation of the
improved BCU classifiers on a large test system
and on the actual PJM interconnection system
for a fast screening has been performed. This
evaluation study is the largest in terms of system
size, 14,500 buses and 3,000 generators, for a
practical online transient stability assessment
application. The evaluation results, performed
on a total number of 5.3 million contingencies,
were very promising in terms of speed, accuracy,
reliability, and robustness (Chiang et al. 2013).
This study also confirms the practicality of
theory-based methodology for online transient
stability assessment of large-scale power
systems; in particular, theory-based methods are
suitable for power system online applications
which demand speed, accuracy, reliability, and
robustness.

Lyapunov's Stability Theory

Hassan K. Khalil
Department of Electrical and Computer Engineering, Michigan State University, East Lansing, MI, USA

Abstract

Lyapunov's theory for characterizing and studying the stability of equilibrium points is presented for time-invariant and time-varying systems modeled by ordinary differential equations.

Keywords

Asymptotic stability; Equilibrium point; Exponential stability; Global asymptotic stability; Hurwitz matrix; Invariance principle; Linearization; Lipschitz condition; Lyapunov function; Lyapunov surface; Negative (semi-) definite function; Perturbed system; Positive (semi-) definite function; Region of attraction; Stability; Time-invariant system; Time-varying system

Introduction

Stability theory plays a central role in systems theory and engineering. For systems represented by state models, stability is characterized by studying the asymptotic behavior of the state variables near steady-state solutions, like equilibrium points or periodic orbits. In this article, Lyapunov's method for determining the stability of equilibrium points is introduced. The attractive features of the method include a solid

theoretical foundation, the ability to conclude stability without knowledge of the solution (no extensive simulation effort), and an analytical framework that makes it possible to study the effect of model perturbations and design feedback control. Its main drawback is the need to search for an auxiliary function that satisfies certain conditions.

Stability of Equilibrium Points

We consider a nonlinear system represented by the state model

$$\dot{x} = f(x) \tag{1}$$

where the n-dimensional **locally Lipschitz** function $f(x)$ is defined for all x in a domain $D \subset R^n$. A function $f(x)$ is locally Lipschitz at a point x_0 if it satisfies the **Lipschitz condition** $\|f(x) - f(y)\| \leq L\|x - y\|$ for all x, y in some neighborhood of x_0, where L is a positive constant and $\|x\| = \sqrt{x_1^2 + x_2^2 + \cdots + x_n^2}$. The Lipschitz condition guarantees that Eq. (1) has a unique solution for given initial state $x(0)$. Suppose $\bar{x} \in D$ is an **equilibrium point** of Eq. (1); that is, $f(\bar{x}) = 0$. Whenever the state of the system starts at $\bar{x}$, it will remain at $\bar{x}$ for all future time. Our goal is to characterize and study the stability of $\bar{x}$. For convenience, we take $\bar{x} = 0$. There is no loss of generality in doing so because any equilibrium point $\bar{x}$ can be shifted to the origin via the change of variables $y = x - \bar{x}$. Therefore, we shall always assume that $f(0) = 0$ and study stability of the origin $x = 0$.

The equilibrium point $x = 0$ of Eq. (1) is **stable** if for each $\varepsilon > 0$, there is $\delta = \delta(\varepsilon) > 0$ such that $\|x(0)\| < \delta$ implies that $\|x(t)\| < \varepsilon$, for all $t \geq 0$. It is **asymptotically stable** if it is stable and δ can be chosen such that $\|x(0)\| < \delta$ implies that $x(t)$ converges to the origin as t tends to infinity. When the origin is asymptotically stable, the **region of attraction** (also called region of asymptotic stability, domain of attraction, or basin) is defined as the set of all points x such that the solution of Eq. (1) that starts from x at

time $t = 0$ approaches the origin as t tends to ∞. When the region of attraction is the whole space, we say that the origin is **globally asymptotically stable**. A stronger form of asymptotic stability arises when there exist positive constants c, k, and λ such that the solutions of Eq. (1) satisfy the inequality

$$\|x(t)\| \leq k\|x(0)\|e^{-\lambda t}, \quad \forall \, t \geq 0 \tag{2}$$

for all $\|x(0)\| < c$. In this case, the equilibrium point $x = 0$ is said to be **exponentially stable**. It is said to be globally exponentially stable if the inequality is satisfied for any initial state $x(0)$.

Linear Systems
For the linear time-invariant system

$$\dot{x} = Ax \tag{3}$$

the stability properties of the origin can be determined by the location of the eigenvalues of A. The origin is stable if and only if all the eigenvalues of A satisfy $\text{Re}[\lambda_i] \leq 0$ and for every eigenvalue with $\text{Re}[\lambda_i] = 0$ and algebraic multiplicity $q_i \geq 2$, $\text{rank}(A - \lambda_i I) = n - q_i$, where n is the dimension of x and q_i is the multiplicity of λ_i as a zero of $\det(\lambda I - A)$. The origin is globally exponentially stable if and only if all eigenvalues of A have negative real parts; that is, A is a **Hurwitz matrix**. For linear systems, the notions of asymptotic and exponential stability are equivalent because the solution is formed of exponential modes. Moreover, due to linearity, if the origin is exponentially stable, then the inequality of Eq. (2) will hold for all initial states.

Linearization
Suppose the function $f(x)$ of Eq. (1) is continuously differentiable in a domain D containing the origin. The Jacobian matrix $[\partial f/\partial x]$ is an $n \times n$ matrix whose (i, j) element is $\partial f_i/\partial x_j$. Let A be the Jacobian matrix evaluated at the origin $x = 0$. It can be shown that

$$f(x) = [A + G(x)]x, \quad \text{where } \lim_{x \to 0} G(x) = 0$$

This suggests that in a small neighborhood of the origin we can approximate the nonlinear system $\dot{x} = f(x)$ by its linearization about the origin $\dot{x} = Ax$. Indeed, we can draw conclusions about the stability of the origin as an equilibrium point for the nonlinear system by examining the eigenvalues of A. The origin of Eq. (1) is exponentially stable if and only if A is Hurwitz. It is unstable if $\text{Re}[\lambda_i] > 0$ for one or more of the eigenvalues of A. If $\text{Re}[\lambda_i] \leq 0$ for all i, with $\text{Re}[\lambda_i] = 0$ for some i, we cannot draw a conclusion about the stability of the origin of Eq. (1).

Lyapunov's Method

Let $V(x)$ be a continuously differentiable scalar function defined in a domain $D \subset R^n$ that contains the origin. The function $V(x)$ is said to be **positive definite** if $V(0) = 0$ and $V(x) > 0$ for $x \neq 0$. It is said to be **positive semidefinite** if $V(x) \geq 0$ for all x. A function $V(x)$ is said to be **negative definite** or **negative semidefinite** if $-V(x)$ is positive definite or positive semidefinite, respectively. The derivative of V along the trajectories of Eq. (1) is given by

$$\dot{V}(x) = \sum_{i=1}^{n} \frac{\partial V}{\partial x_i} \dot{x}_i = \frac{\partial V}{\partial x} f(x)$$

where $[\partial V/\partial x]$ is a row vector whose ith component is $\partial V/\partial x_i$.

Lyapunov's stability theorem states that *the origin is stable if there is a continuously differentiable positive definite function $V(x)$ so that $\dot{V}(x)$ is negative semidefinite, and it is asymptotically stable if $\dot{V}(x)$ is negative definite*. A function $V(x)$ satisfying the conditions for stability is called a **Lyapunov function**. The surface $V(x) = c$, for some $c > 0$, is called a **Lyapunov surface** or a level surface.

When $\dot{V}(x)$ is only negative semidefinite, we may still conclude asymptotic stability of the origin if we can show that no solution can stay identically in the set $\{\dot{V}(x) = 0\}$, other than the zero solution $x(t) \equiv 0$. Under this condition, $V(x(t))$ must decrease toward 0, and consequently $x(t)$

converges to zero as t tends to infinity. This extension of the basic theorem is known as **the invariance principle**.

Lyapunov functions can be used to estimate the region of attraction of an asymptotically stable origin, that is, to find sets contained in the region of attraction. Let $V(x)$ be a Lyapunov function that satisfies the conditions of asymptotic stability over a domain D. For a positive constant c, let Ω_c be the component of $\{V(x) \leq c\}$ that contains the origin in its interior. The properties of V guarantee that, by choosing c small enough, Ω_c will be bounded and contained in D. Then, every trajectory starting in Ω_c remains in Ω_c and approaches the origin as $t \to \infty$. Thus, Ω_c is an estimate of the region of attraction. If $D = R^n$ and $V(x)$ is radially unbounded, that is, $\|x\| \to \infty$ implies that $V(x) \to \infty$, then any point $x \in R^n$ can be included in a bounded set Ω_c by choosing c large enough. Therefore, *the origin is globally asymptotically stable if there is a continuously differentiable, radially unbounded function $V(x)$ such that for all $x \in R^n$, $V(x)$ is positive definite and $\dot{V}(x)$ is either negative definite or negative semidefinite but no solution can stay identically in the set $\{\dot{V}(x) = 0\}$ other than the zero solution $x(t) \equiv 0$.*

Time-Varying Systems

Equation (1) is time-invariant because f does not depend on t. The more general time-varying system is represented by

$$\dot{x} = f(t, x) \tag{4}$$

In this case, we may allow the Lyapunov function candidate V to depend on t. Let $V(t, x)$ be a continuously differentiable function defined for all $t \geq 0$ and $x \in D$. The derivative of V along the trajectories of Eq. (4) is given by

$$\dot{V}(t, x) = \frac{\partial V}{\partial t} + \frac{\partial V}{\partial x} f(t, x)$$

If there are positive definite functions $W_1(x)$, $W_2(x)$, and $W_3(x)$ such that

$$W_1(x) \leq V(t, x) \leq W_2(x) \tag{5}$$

$$\dot{V}(t, x) \leq -W_3(x) \tag{6}$$

for all $t \geq 0$ and all $x \in D$, then the origin is uniformly asymptotically stable, where "uniformly" indicates that the ε–δ definition of stability and the convergence of $x(t)$ to zero are independent of the initial time t_0. Such uniformity annotation is not needed with time-invariant systems since the solution of a time-invariant state equation starting at time t_0 depends only on the difference $t - t_0$, which is not the case for time-varying systems. If the inequalities of Eqs. (5) and (6) hold globally and $W_1(x)$ is radially unbounded, then the origin is globally uniformly asymptotically stable. If $W_1(x) = k_1\|x\|^a$, $W_2(x) = k_2\|x\|^a$, and $W_3(x) = k_3\|x\|^a$ for some positive constants k_1, k_2, k_3, and a, then the origin is exponentially stable.

Perturbed Systems

Consider the system

$$\dot{x} = f(t, x) + g(t, x) \qquad (7)$$

where f and g are continuous in t and locally Lipschitz in x, for all $t \geq 0$ and $x \in D$, in which $D \subset R^n$ is a domain that contains the origin $x = 0$. Suppose $f(t, 0) = 0$ and $g(t, 0) = 0$ so that the origin is an equilibrium point of Eq. (7). We think of the system (7) as a perturbation of the nominal system (4). The perturbation term $g(t, x)$ could result from modeling errors, uncertainties, or disturbances. In a typical situation, we do not know $g(t, x)$, but we know some information about it, like knowing an upper bound on $\|g(t, x)\|$. Suppose the nominal system has an exponentially stable equilibrium point at the origin, what can we say about the stability of the origin as an equilibrium point of the perturbed system? A natural approach to address this question is to use a Lyapunov function for the nominal system as a Lyapunov function candidate for the perturbed system.

Let $V(t, x)$ be a Lyapunov function that satisfies

$$c_1\|x\|^2 \leq V(t, x) \leq c_2\|x\|^2 \qquad (8)$$

$$\frac{\partial V}{\partial t} + \frac{\partial V}{\partial x} f(t, x) \leq -c_3\|x\|^2 \qquad (9)$$

$$\left\| \frac{\partial V}{\partial x} \right\| \leq c_4\|x\| \qquad (10)$$

for all $x \in D$ for some positive constants c_1, c_2, c_3, and c_4. Suppose the perturbation term $g(t, x)$ satisfies the linear growth bound

$$\|g(t, x)\| \leq \gamma\|x\|, \quad \forall\, t \geq 0, \ \forall\, x \in D \qquad (11)$$

where γ is a nonnegative constant. We use V as a Lyapunov function candidate to investigate the stability of the origin as an equilibrium point for the perturbed system. The derivative of V along the trajectories of Eq. (7) is given by

$$\dot{V}(t, x) = \frac{\partial V}{\partial t} + \frac{\partial V}{\partial x} f(t, x) + \frac{\partial V}{\partial x} g(t, x)$$

The first two terms on the right-hand side are the derivative of $V(t, x)$ along the trajectories of the nominal system, which is negative definite and satisfies the inequality of Eq. (9). The third term, $[\partial V/\partial x]g$, is the effect of the perturbation. Using Eqs. (9) through (11), we obtain

$$\dot{V}(t, x) \leq -c_3\|x\|^2 + \left\| \frac{\partial V}{\partial x} \right\| \|g(t, x)\|$$

$$\leq -c_3\|x\|^2 + c_4\gamma\|x\|^2$$

If $\gamma < c_3/c_4$, then

$$\leq -(c_3 - \gamma c_4)\|x\|^2, \ \ (c_3 - \gamma c_4) > 0$$

which shows that the origin is an exponentially stable equilibrium point of the perturbed system (7).

Summary

Lyapunov's method is a powerful tool for studying the stability of equilibrium points. However, there are two drawbacks of the method. First,

there is no systematic procedure for finding Lyapunov functions. Second, the conditions of the theory are only sufficient; they are not necessary. Failure of a Lyapunov function candidate to satisfy the conditions for stability or asymptotic stability does not mean that the origin is not stable or asymptotically stable. These drawbacks have been mitigated by a long history of using the method in the analysis and design of engineering systems, where various techniques for finding Lyapunov functions for specific systems have been determined.

Markov Chains and Ranking Problems in Web Search

Hideaki Ishii[1] and Roberto Tempo[2]
[1]Tokyo Institute of Technology, Yokohama, Japan
[2]CNR-IEIIT, Politecnico di Torino, Torino, Italy

Abstract

Markov chains refer to stochastic processes whose states change according to transition probabilities determined only by the states of the previous time step. They have been crucial for modeling large-scale systems with random behavior in various fields such. as control, communications, biology, optimization, and economics. In this entry, we focus on their recent application to the area of search engines, namely, the PageRank algorithm employed at Google, which provides a measure of importance for each page in the web. We present several researches carried out with control theoretic tools such as aggregation, distributed randomized algorithms, and PageRank optimization. Due to the large size of the web, computational issues are the underlying motivation of these studies.

Keywords

Aggregation; Distributed randomized algorithms; Markov chains; Optimization; PageRank; Search engines; World wide web

Introduction

For various real-world large-scale dynamical systems, reasonable models describing highly complex behaviors can be expressed as stochastic systems, and one of the most well-studied classes of such systems is that of Markov chains. A characteristic feature of Markov chains is that their behavior does not carry any memory. That is, the current state of a chain is completely determined by the state of the previous time step and not at all on the states prior to that step (Kumar and Varaiya 1986; Norris 1997).

Recently, Markov chains have gained renewed interest due to the extremely successful applications in the area of web search. The search engine of Google has been employing an algorithm known as PageRank to assist the ranking of search results. This algorithm models the network of web pages as a Markov chain whose states represent the pages that web surfers with various interests visit in a random fashion. The objective is to find an order among the pages according to their

popularity and importance, and this is done by focusing on the structure of hyperlinks among pages.

In this entry, we first provide a brief overview on the basics of Markov chains and then introduce the problem of PageRank computation. We proceed to provide further discussions on control theoretic approaches dealing with PageRank problems. The topics covered include aggregated Markov chains, distributed randomized algorithms, and Markov decision problems for link optimization.

Markov Chains

In the simplest form, a Markov chain takes its states in a finite state space with transitions in the discrete-time domain. The transition from one state to another is characterized completely by the underlying probability distribution.

Let $\mathcal{X}$ be a finite set given by $\mathcal{X} := \{1, 2, \ldots, n\}$, which is called the state space. Consider a stochastic process $\{X_k\}_{k=0}^{\infty}$ taking values on this set $\mathcal{X}$. Such a process is called a Markov chain if it exhibits the following Markov property:

$$\text{Prob}\{X_{k+1} = j | X_k = i_k, \ X_{k-1} = i_{k-1}, \ldots, $$
$$X_0 = i_0\} = \text{Prob}\{X_{k+1} = j | X_k = i_k\},$$

where $\text{Prob}\{\cdot | \cdot\}$ denotes the conditional probability and $k \in \mathbb{Z}_+$. That is, the state at the next time step depends only on the current state and not those of previous times.

Here, we consider the homogeneous case where the transition probability is constant over time. Thus, we have for each pair $i, j \in \mathcal{X}$, the probability that the chain goes from state j to state i at time k expressed as

$$p_{ij} := \text{Prob}\{X_k = i | X_{k-1} = j\}, \ k \in \mathbb{Z}_+.$$

In the matrix form, $P := (p_{ij})$ is called the transition probability matrix of the chain. It is obvious that all entries of P are nonnegative, and for each j, the entries of the jth column of P

sum up to 1, i.e., $\sum_{i=1}^{n} p_{ij} = 1$ for $j \in \mathcal{X}$. In this respect, the matrix P is (column) stochastic (Horn and Johnson 1985).

In this entry, we assume that the Markov chain is ergodic, meaning that for any pair of states, the chain can make a transition from one to the other over time. In this case, the chain and the matrix P are called irreducible. This property is known to imply that P has a simple eigenvalue of 1. Thus, there exists a unique steady state probability distribution $\pi \in \mathbb{R}^n$ given by

$$\pi = P\pi, \ \ \mathbf{1}^T \pi = 1, \ \ \pi_i > 0, \ \forall i \in \mathcal{X},$$

where $\mathbf{1} \in \mathbb{R}^n$ denotes a vector with entries one. Note that in this distribution π, all entries are positive.

Ranking in Search Engines: PageRank Algorithm

At Google, PageRank is used to quantify the importance of each web page based on the hyperlink structure of the web (Brin and Page 1998; Langville and Meyer 2006). A page is considered important if (i) many pages have links pointing to the page, (ii) such pages having links are important ones, and (iii) the numbers of links that such pages have are limited. Intuitively, these requirements are reasonable. For a web page, its incoming links can be viewed as votes supporting the page, and moreover the quality of the votes count through their importance as well as the number of votes that they make. Even if a minor page (with low PageRank) has many outgoing links, its contribution to the linked pages will not be substantial.

An interesting way to explain the PageRank is through the *random surfer model*: The random surfer starts from a randomly chosen page. Each time visiting a page, he/she follows a hyperlink in that page chosen at random with uniform probability. Hence, if the current page i has n_i outgoing links, then one of them is picked with probability $1/n_i$. If it happens that the current page has no outgoing link (e.g., at PDF documents), the surfer will use the back button. This process

will be repeated. The PageRank value for a page represents the probability of the surfer visiting the page. It is thus higher for pages visited more often by the surfer.

It is now clear that PageRank is obtained by describing the random surfer model as a Markov chain and then finding its stationary distribution. First, we express the network of web pages as the directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} = \{1, 2, \ldots, n\}$ is the set of nodes corresponding to web page indices while $\mathcal{E} \subset \mathcal{V} \times \mathcal{V}$ is the set of edges for links among pages. Node i is connected to node j by an edge, i.e., $(i, j) \in \mathcal{E}$, if page i has an outgoing link to page j.

Let $x_i(k)$ be the distribution of the random surfer visiting page i at time k, and let $x(k)$ be the vector containing all $x_i(k)$. Given the initial distribution $x(0)$, which is a probability vector, i.e., $\sum_{i=1}^{n} x_i(0) = 1$, the evolution of $x(k)$ can be expressed as

$$x(k + 1) = Ax(k). \tag{1}$$

The link matrix $A = (a_{ij}) \in \mathbb{R}^{n \times n}$ is given by $a_{ij} = 1/n_j$ if $(j, i) \in \mathcal{E}$ and 0 otherwise, where n_j is the number of outgoing links of page j. Note that this matrix A is the transition probability matrix of the random surfer. Clearly, it is stochastic, and thus $x(k)$ remains a probability vector so that $\sum_{i=1}^{n} x_i(k) = 1$ for all k.

As mentioned above, PageRank is the stationary distribution of the process (1) under the assumption that the limit exists. Hence, the PageRank vector is given by $x^* := \lim_{k \to \infty} x(k)$. In other words, it is the solution of the linear equation

$$x^* = Ax^*, \quad x^* \in [0, 1]^n, \quad \mathbf{1}^T x^* = 1. \tag{2}$$

Notice that the PageRank vector x^* is a nonnegative unit eigenvector for the eigenvalue 1 of A. Such a vector exists since the matrix A is stochastic, but may not be unique; the reason is that A is a reducible matrix since in the web, not every pair of pages can be connected by simply following links. To resolve this issue, a slight modification is necessary in the random surfer model.

The idea of the *teleportation model* is that the random surfer, after a while, becomes bored and stops following the hyperlinks. At such an instant, the surfer "jumps" to another page not directly connected to the one currently visiting. This page can be in fact completely unrelated in the domains and/or the contents. All n pages in the web have the same probability $1/n$ to be reached by a jump.

The probability to make such a jump is denoted by $m \in (0, 1)$. The original transition probability matrix A is now replaced with the modified one $M \in \mathbb{R}^{n \times n}$ defined by

$$M := (1 - m)A + \frac{m}{n}\mathbf{1}\mathbf{1}^T. \tag{3}$$

For the value of m, we take $m = 0.15$ as reported in the original algorithm in Brin and Page (1998). Notice that M is a positive stochastic matrix. By Perron's theorem (Horn and Johnson 1985), the eigenvalue 1 is of multiplicity 1 and is the unique eigenvalue with the maximum modulus. Further, the corresponding eigenvector is positive. Hence, we redefine the vector x^* in (2) by using M instead of A as follows:

$$x^* = Mx^*, \quad x^* \in [0, 1]^n, \quad \mathbf{1}^T x_i^* = 1.$$

Due to the large dimension of the link matrix M, the computation of x^* is difficult. The solution employed in practice is based on the power method given by

$$x(k + 1) = Mx(k) = (1 - m)Ax(k) + \frac{m}{n}\mathbf{1}, \tag{4}$$

where the initial vector $x(0) \in \mathbb{R}^n$ is a probability vector. The second equality above follows from the fact $\mathbf{1}^T x(k) = 1$ for $k \in \mathbb{Z}_+$. For implementation, the form on the far right-hand side is important, using only the sparse matrix A and not the dense matrix M. This method asymptotically finds the value vector as $x(k) \to x^*, k \to \infty$.

Aggregation Methods for Large-Scale Markov Chains

In dealing with large-scale Markov chains, it is often desirable to predict their dynamic behaviors from reduced-order models that are more computationally tractable. This enables us, for example, to analyze the system performance at a macroscale with some approximation under different operating conditions. Aggregation refers to partitioning or grouping the states so that the states in each group can be treated as a whole. The technique of aggregation is especially effective for Markov chains possessing sparse structures with strong interactions among states in the same group and weak interactions among states in different groups. Such methods have been extensively studied, motivated by applications in queueing networks, power systems, etc. (Meyer 1989).

In the context of the PageRank problem, such sparse interconnection can be expressed in the link matrix A with a block-diagonal structure (after some coordinate change, if necessary). The entries of the matrix A are dense along its diagonal in blocks, and those outside the blocks take small values. More concretely, we write

$$A = I + B + \epsilon C, \qquad (5)$$

where B is a block-diagonal matrix given as $B = \mathrm{diag}(B_{11}, B_{22}, \ldots, B_{NN})$; B_{ii} is the $\tilde{n}_i \times \tilde{n}_i$ matrix corresponding to the ith group with $\tilde{n}_i$ member pages for $i = 1, 2, \ldots, N$; and ϵ is a small positive parameter. Here, the non-diagonal entries of B_{ii} are the same as those in the same diagonal block of A, but the diagonal entries are chosen such that $I + B_{ii}$ becomes stochastic and thus take nonpositive values. Thus, both B and C have column sums equal to zero. The small ϵ suggests us that states can be aggregated into N groups with strong interactions within the groups, but connections among different groups are weak. This class of Markov chains is known as nearly completely decomposable. In general, however, it is difficult to uniquely determine the form (5) for a given chain.

To exploit the sparse structure in the computation of stationary probability distributions, one approach is to carry out decomposition or aggregation of the chains. The basic approach here is (i) to compute the local stationary distributions for $I + B_{ii}$, (ii) to find the global stationary distribution for a chain representing the group interactions, and (iii) to finally use the obtained vectors to compute exact/approximate distribution for the entire chain; for details, see Meyer (1989). By interpreting such methods from the control theoretic viewpoints, in Phillips and Kokotovic (1981) and Aldhaheri and Khalil (1991), singular perturbation approaches have been developed. These methods lead us to the two-time scale decomposition of (controlled) Markov chain recursions.

In the case of PageRank computation, sparsity is a relevant property since it is well known that many links in the web are intra-host ones, connecting pages within the same domains or directories. However, in the real web, it is easy to find pages that have only a few outlinks, but some of them are external ones. Such pages will prevent the link matrix from having small ϵ when decomposed in the form (5). Hence, the general aggregation methods outlined above are not directly applicable.

An aggregation-based method suitable for PageRank computation is proposed in Ishii et al. (2012). There, the sparsity in the web is expressed by the limited number of external links pointing towards pages in other groups. For each page i, the node parameter $\delta_i \in [0, 1]$ is given by

$$\delta_i := \frac{\text{\# external outgoing links}}{\text{\# total outgoing links}}.$$

Note that smaller δ_i implies sparser networks. In this approach, for a given bound δ, the condition $\delta_i \leq \delta$ is imposed only in the case page i belongs to a group consisting of multiple members. Thus, a page forming a group by itself is not required to satisfy the condition. This means that we can regroup the pages by first identifying pages that violate this condition in the initial groups and then making them separately as *single* groups. By repeating these steps, it is always possible to

obtain groups for a given web. Once the grouping is settled, an aggregation-based algorithm can be applied, which computes an approximated PageRank vector. A characteristic feature is the tradeoff between the accuracy in PageRank computation and the node parameter δ. More accurate computation requires a larger number of groups and thus a smaller δ.

Distributed Randomized Computation

For large-scale computation, distributed algorithms can be effective by employing multiple processors to compute in parallel. There are several methods of constructing algorithms to find stationary distributions of large Markov chains. In this section, motivated by the current literature on multi-agent systems, sequential distributed randomized approaches of gossip type are described for the PageRank problem.

In *gossip-type* distributed algorithms, nodes make decisions and transmit information to their neighbors in a random fashion. That is, at any time instant, each node decides whether to communicate or not depending on a random variable. The random property is important to make the communication asynchronous so that simultaneous transmissions resulting in collisions can be avoided. Moreover, there is no need of any centralized decision maker or fixed order among pages.

More precisely, each page $i \in \mathcal{V}$ is equipped with a random process $\eta_i(k) \in \{0, 1\}$ for $k \in \mathbb{Z}_+$. If at time k, $\eta_i(k)$ is equal to 1, then page i broadcasts its information to its neighboring pages connected by outgoing links. All pages involved at this time renew their values based on the latest available data. Here, $\eta_i(k)$ is assumed to be an independent and identically distributed (i.i.d.) random process, and its probability distribution is given by Prob$\{\eta_i(k) = 1\} = \alpha$, $k \in \mathbb{Z}_+$. Hence, all pages are given the same probability α to initiate an update.

One of the proposed randomized approaches is based on the so-called asynchronous iteration algorithms for distributed computation of fixed points in the field of numerical analysis (Bertsekas and Tsitsiklis 1989). The distributed update recursion is given as

$$\check{x}(k+1) = \check{M}_{\eta_1(k),\ldots,\eta_n(k)}\check{x}(k), \qquad (6)$$

where the initial state $\check{x}(0)$ is a probability vector and the distributed link matrices $\check{M}_{p_1,\ldots,p_n}$ are given as follows: Its (i, j)th entry is equal to $(1-m)a_{ij} + m/n$ if $p_i = 1$; 1 if $p_i = 0$ and $i = j$; and 0 otherwise. Clearly, these matrices keep the rows of the original link matrix M in (3) for pages initiating updates. Other pages just keep their previous values. Thus, these matrices are not stochastic. From this update recursion, the PageRank x^* is probabilistically obtained (in the mean square sense and in probability one), where the convergence speed is exponential in time k. Note that in this scheme (6), due to the way the distributed link matrices are constructed, each page needs to know which pages have links pointing towards it. This implies that popular pages linked by a number of pages must have extra memory to keep the data of such links.

Another recently developed approach Ishii and Tempo (2010) and Zhao et al. (2013) has several notable differences from the asynchronous iteration approach above. First, the pages need to transmit their states only over their outgoing links; the information of such links are by default available locally, and thus, pages are not required to have the extra memory regarding incoming links. Second, it employs stochastic matrices in the update as in the centralized scheme; this aspect is utilized in the convergence analysis. As a consequence, it is established that the PageRank vector x^* is computed in a probabilistic sense through the time average of the states $x(0), \ldots, x(k)$ given by $y(k) := 1/(k+1) \sum_{\ell=0}^{k} x(\ell)$. The convergence speed in this case is of order $1/k$.

PageRank Optimization via Hyperlink Designs

For owners of websites, it is of particular interest to raise the PageRank values of their web pages. Especially in the area of e-business, this can

be critical for increasing the number of visitors to their sites. The values of PageRank can be affected by changing the structure of hyperlinks in the owned pages. Based on the random surfer model, intuitively, it makes sense to arrange the links so that surfers will stay within the domain of the owners as long as possible.

PageRank optimization problems have rigorously been considered in, for example, de Kerchove et al. (2008) and Fercoq et al. (2013). In general, these are combinatorial optimization problems since they deal with the issues on where to place hyperlinks, and thus the computation for solving them can be prohibitive especially when the web data is large. However, the work Fercoq et al. (2013) has shown that the problem can be solved in polynomial time. In what follows, we discuss a simplified discrete version of the problem setup of this work.

Consider a subset $\mathcal{V}_0 \subset \mathcal{V}$ of web pages over which a webmaster has control. The objective is to maximize the total PageRank of the pages in this set $\mathcal{V}_0$ by finding the outgoing links from these pages. Each page $i \in \mathcal{V}_0$ may have constraints such as links that must be placed within the page and those that cannot be allowed. All other links, i.e., those that one can decide to have or not, are the design parameters. Hence, the PageRank optimization problem can be stated as

$$\max\{U(x^*, M) : \ x^* = M x^*, \ x^* \in [0, 1]^n,$$
$$\mathbf{1}^T x^* = 1, \ M \in \mathcal{M}\},$$

where U is the utility function $U(x^*, M) := \sum_{i \in \mathcal{V}_0} x_i^*$ and $\mathcal{M}$ represents the set of admissible link matrices in accordance with the constraints introduced above.

In Fercoq et al. (2013), an extended continuous problem is also studied where the set $\mathcal{M}$ of link matrices is a polytope of stochastic matrices and a more general utility function is employed. The motivation for such a problem comes from having weighted links so that webmasters can determine which links should be placed in a more visible location inside their pages to increase clickings on those hyperlinks. Both discrete and continuous problems are shown to be solvable

in polynomial time by modeling them as constrained Markov decision processes with ergodic rewards (see, e.g., Puterman 1994).

Summary and Future Directions

Markov chains form one of the simplest classes of stochastic processes but have been found powerful in their capability to model large-scale complex systems. In this entry, we introduced them mainly from the viewpoint of PageRank algorithms in the area of search engines and with a particular emphasis on recent works carried out based on control theoretic tools. Computational issues will remain in this area as major challenges, and further studies will be needed. As we have observed in PageRank-related problems, it is important to pay careful attention to structures of the particular problems.

Mathematical Models of Marine Vehicle-Manipulator Systems

Gianluca Antonelli
University of Cassino and Southern Lazio, Cassino, Italy

Abstract

Marine intervention requires the use of manipulators mounted on support vehicles. Such systems, defined as vehicle-manipulator systems, exhibit specific mathematical properties and require proper control design methodologies. This article briefly discusses the mathematical model within a control perspective as well as sensing and actuation peculiarities.

Keywords

Floating-base manipulators; Marine robotics; Underwater intervention; Underwater robotics

Introduction

In case of marine operations that require interaction with the environment, an underwater vehicle is usually equipped with one or more manipulators; such systems are defined underwater vehicle-manipulator systems (UVMSs). A UVMS holding six degree-of-freedom (DOF) manipulators is illustrated in Fig. 1. The vehicle carrying the manipulator may or may not be connected to the surface; in the first case we face a so-called remotely operated vehicle (ROV), while in the latter an autonomous underwater vehicle (AUV). ROVs, being physically linked, via the tether, to an operator that can be on a submarine or on a surface ship, receives power as well as control commands. AUVs, on the other hand, are supposed to be completely autonomous, thus relying to onboard power system and *intelligence*.

Remotely controlled UVMSs represent the state of the art in underwater manipulation, while autonomous or semiautonomous UVMSs still are in their embryonic stage. All over the world, few experimental setups have been developed within on-purpose projects; see, e.g., the European project Trident (2012).

Sensory System

Any manipulation task requires that some variables are measured; those may concern the internal state of the system such as the end effector as well the vehicle position and orientation or the velocities. Some others concern the surrounding environment as it is the case of vision systems or range measurements. Underwater sensing is characterized by poorer performance with respect to the ground corresponding variables due to the physical properties of the water as medium carrying the electromagnetic or acoustic signals.

One of the major challenges in underwater robotics is the localization due to the absence of a single, proprioceptive sensor that measures the vehicle position and the impossibility to use the Global Navigation Satellite System (GNSS) under the water. The use of redundant multisensor systems, thus, is common in order to perform sensor fusion and give fault detection and tolerance capabilities to the vehicle.
Mathematical Models of Marine Vehicle-Manipulator Systems, Fig. 1 Sketch of a UVMS, the inertial frame as well as the frames attached to all the rigid bodies are highlighted

Localization

A possible approach for AUV localization is to rely on inertial navigation systems (INSs); those are algorithms that implement dead reckoning techniques, i.e., the estimation of the position by properly merging and integrating measurements obtained with inertial and velocity sensors. Dead reckoning suffers from numerical drift due to the integration of sensor noise, as well as sensor bias and drift, and may be prone to the presence of external currents and model uncertainties. Since the variance of the estimation error grows with the distance traveled, this technique is only used for short dives.

Several algorithms are based on the concept of trilateration. The vehicle measures its distance with respect to known positions and properly uses this information by applying geometric-based formulas. Under the water, the technology for trilateration is not based on the electromagnetic field, due to the attenuation of its radiations, but on acoustics.

Among the commercially available solutions, long, short, and ultrashort baseline systems have found widespread use. The differences are in the baseline wavelength, the required distance among the transponders, the accuracy, and the installation cost. Acoustic underwater positioning is commercially mature, and several companies offer a variety of products.

In case of intervention, when the UVMS is close to the target, rather than the absolute position with respect to an inertial frame, it is crucial to estimate the relative position with respect to the target itself. In such a case, vision-based systems may be considered.

Actuation

Underwater vehicles are usually controlled by thrusters and/or control surfaces. Control surfaces, such as rudders and sterns, are typically used in vehicles working at cruise speed, i.e., torpedo-shaped vehicles usually used in

monitoring or cable/pipeline inspection. In such vehicles a main thruster is used together with at least one rudder and one stern.

This configuration is unsuitable for UVMSs since the force/moment provided by the control surfaces is the function of the velocity and it is null in hovering, when typically manipulation is performed.

The relationship between the force/moment acting on the vehicle and the control input of the thrusters is highly nonlinear. It is the function of structural variables such as the density of the water, the tunnel cross-sectional area, the tunnel length, the volumetric flow rate between input and output of the thrusters, and the propeller diameter. The state of the dynamic system describing the thrusters is constituted by the propeller revolution, the speed of the fluid going into the propeller, and the input torque.

Modeling

UVMSs can be modeled as rigid bodies connected to form a serial chain; the vehicle is the floating base, while each link of the manipulator represents an additional rigid body with one DOF, typically the rotation around the corresponding joint's axis. Roughly speaking, modeling of a UVMS is the effort to represent the physical relationships of those bodies in order to measure and control its end effector, typically involved in a manipulation task.

The first step of modeling is the so-called direct kinematics, consisting in computing the position/orientation of the end effector with respect to an inertial, i.e., world fixed, frame. This is done via geometric relationship function of the system kinematic parameters, typically the lengths of the links, and the current system configuration, i.e., the vehicle position/orientation and the joint positions.

Velocities of each rigid body affect the following rigid bodies and thus the end effector. For example, a vehicle roll movement or the joint velocity is projected into a linear and angular end-effector velocity. This velocity transformation is studied by the differential kinematics.

Analytic and/or geometric approaches may be used to retrieve those relationships. The study of the velocity-related equations is fundamental to understand how to balance the movement between vehicle and manipulator and, within the manipulator, how to distribute it among the joints. This topic is strictly related to differential, and inverse, kinematics for industrial robots.

The extension of Newton's second law to UVMSs leads to a number of nonlinear differential equations that link together the systems generalized forces and accelerations. With the word generalized forces, it is here intended as the forces and moments acting on the vehicles and the joint torques. Correspondingly, one is interested in the vehicle linear and angular accelerations and joint accelerations. Those equations couple together all the DOFs of the structure, e.g., a force applied to the vehicle causes acceleration also on the joints. Study of the dynamics is crucial to design the controller.

It is not possible to neglect that the bodies are moving in the water, the theory of fluidodynamics is rather complex, and it is difficult to develop a *simple* model for most of the hydrodynamic effects. A rigorous analysis for incompressible fluids would need to resort to the Navier-Stokes equations (distributed fluid flow). However, most of the hydrodynamic effects have no significant influence in the range of the operative velocities for UVMS intervention tasks. In particular, it is necessary to model added masses, linear and quadratic damping terms, and the buoyancy.

Control

Not surprisingly, the mathematical model of UVMS shares most of the characteristics of industrial robots as well as space robots modeling. Having taken into account to the physical differences, the control problems are also similar:

- Kinematic control. The control problem is given in terms of motion of the end effector and needs to be transformed into the motion of the vehicle and the manipulator. This is often approached by resorting to the inverse

differential kinematic algorithms. In particular, algorithms for redundant systems need to be considered since a UVMS always possess at least six DOFs. Moving a UVMS requires to handle additional variables with respect to the end effector such as the vehicle roll and pitch to preserve energy, the robot manipulability, the mechanical joint limits, or eventual directional sensing.

- Motion control. Low-level control algorithms are designed to allow the system tracking the desired trajectory. UVMSs are characterized by different dynamics between vehicle and manipulator, uncertainty in the model parameter knowledge, poor sensing performance, and limit cycle in the thruster model. On the other hand, the limited bandwidth of the closed-loop system allows the use of simple control approaches.

- Interaction control. Several applications require exchange of forces with the environment. A pure motion control algorithm is not devised for such operation and specific force control algorithms, both direct and indirect, may be necessary. Master/slave systems or haptic devices may be used on the purpose, while autonomous interaction control still is in the research phase for the marine environment.

Summary and Future Directions

This article is aimed at giving a short overview of the main mathematical and technological challenges arising with UVMSs. All the components of an underwater mission, perception, actuation, and communication with the surface, are characterized by poorer performances with respect to the current industrial or advanced robotics applications.

The underwater environment is hostile; as an example the marine current provides disturbances to be counteracted by the dynamic controller, or the sand's whirlwinds obfuscate the vision-based operations close to the sea bottom. Both tele-operated and autonomous underwater missions require a significant human effort in planning,

testing, and monitoring all the operations. Fault detection and recovery policies are necessary in each step to avoid loss of expensive hardware.

Future generation of UVMSs needs to be autonomous, to percept and contextualize the environment, to react with respect to unplanned situations, and to safely reschedule the tasks of complex missions. Those characteristics are being shared by all the branches of the service robotics.

Mathematical Models of Ships and Underwater Vehicles

Thor I. Fossen
Department of Engineering Cyberentics, Centre for Autonomous Marine Operations and Systems, Norwegian University of Science and Technology, Trondheim, Norway

Abstract

This entry describes the equations of motion of ships and underwater vehicles. Standard hydrodynamic models in the literature are reviewed and presented using the nonlinear robot-like vectorial notation of Fossen (1991, 1994, 2011). The matrix-vector notation is highly advantageous when designing control systems since well-known system properties such as symmetry, skew-symmetry, and positiveness can be exploited in the design.

Keywords

Autonomous underwater vehicle (AUV); Degrees of freedom; Euler angles; Hydrodynamics; Kinematics; Kinetics; Maneuvering; Remotely operated vehicle (ROV); Seakeeping; Ship; Underwater vehicles

Introduction

The subject of this entry is mathematical modeling of ships and underwater vehicles. With *ship* we mean "any large floating vessel capable of crossing open waters," as opposed to a boat, which is generally a smaller craft. An *underwater vehicle* is a "small vehicle that is capable of propelling itself beneath the water surface as well as on the water's surface." This includes unmanned underwater vehicles (UUVs), remotely operated vehicles (ROVs), autonomous underwater vehicles (AUVs) and underwater robotic vehicles (URVs).

This entry is based on Fossen (1991, 2011), which contains a large number of standard models for ships, rigs, and underwater vehicles. There exist a large number of textbooks on mathematical modeling of ships; see Rawson and Tupper (1994), Lewanddowski (2004), and Perez (2005). For underwater vehicles, see Allmendinger (1990), Sutton and Roberts (2006), Inzartsev (2009), Antonelli (2010), and Wadoo and Kachroo (2010). Some useful references on ship hydrodynamics are Newman (1977), Faltinsen (1990), and Bertram (2012).

Degrees of Freedom

A mathematical model of marine craft is usually represented by a set of ordinary differential equations (ODEs) describing the motions in six degrees of freedom (DOF): *surge, sway, heave, roll, pitch,* and *yaw*.

Hydrodynamics

In hydrodynamics it is common to distinguish between two theories:

- **Seakeeping theory:** The motions of ships at zero or constant speed in waves are analyzed using hydrodynamic coefficients and wave forces, which depends of the wave excitation frequency and thus the hull geometry and mass distribution. For underwater vehicles operating below the wave-affected zone, the wave excitation frequency will not influence the hydrodynamic coefficients.

- **Maneuvering theory:** The ship is moving in restricted calm water – that is, in sheltered waters or in a harbor. Hence, the maneuvering model is derived for a ship moving at positive speed under a zero-frequency wave excitation

assumption such that added mass and damping can be represented by constant parameters.

Seakeeping models are typically used for ocean structures and dynamically positioned vessels. Several hundred ODEs are needed to effectively represent a seakeeping model; see Fossen (2011), and Perez and Fossen (2011a,b).

The remainder of this entry assumes *maneuvering theory*, since this gives lower-order models typically suited for controller-observer design. Six ODEs are needed to describe the *kinematics*, that is, the geometrical aspects of motion while Newton-Euler's equations represent additional six ODEs describing the forces and moments causing the motion (*kinetics*).

Notation

The equations of motion are usually represented using generalized position, velocity and forces (Fossen 1991, 1994, 2011) defined by the state vectors:

$$\boldsymbol{\eta} := [x, y, z, \phi, \theta, \psi]^\top \tag{1}$$

$$\boldsymbol{v} := [u, v, w, p, q, r]^\top \tag{2}$$

$$\boldsymbol{\tau} := [X, Y, Z, K, M, N]^\top \tag{3}$$

where $\boldsymbol{\eta}$ is the generalized position expressed in the north-east-down (NED) reference frame $\{n\}$. A body-fixed reference frame $\{b\}$ with axes:

x_b – longitudinal axis (from aft to fore)
y_b – transversal axis (to starboard)
z_b – normal axis (directed downward)
is rotating about the NED reference frame $\{n\}$ with angular velocity $\boldsymbol{\omega} = [p, q, r]^\top$. The generalized velocity vector $\boldsymbol{v}$ and forces $\boldsymbol{\tau}$ are both expressed in $\{b\}$, and the 6-DOF states are defined according to SNAME (1950):

- **Surge** position x, linear velocity u, force X
- **Sway** position y, linear velocity v, force Y
- **Heave** position z, linear velocity w, force Z
- **Roll** angle ϕ, angular velocity p, moment K
- **Pitch** angle θ, angular velocity q, moment M
- **Yaw** angle ψ, angular velocity r, moment N

Kinematics

The generalized velocities $\dot{\boldsymbol{\eta}}$ and $\boldsymbol{v}$ in $\{b\}$ and $\{n\}$, respectively satisfy the following kinematic transformation (Fossen 1994, 2011):

$$\dot{\boldsymbol{\eta}} = \mathbf{J}(\boldsymbol{\eta})\boldsymbol{v} \tag{4}$$

$$\mathbf{J}(\boldsymbol{\eta}) := \begin{bmatrix} \mathbf{R}(\boldsymbol{\Theta}) & \mathbf{0}_{3\times3} \\ \mathbf{0}_{3\times3} & \mathbf{T}(\boldsymbol{\Theta}) \end{bmatrix} \tag{5}$$

where $\boldsymbol{\Theta} = [\phi, \theta, \psi]^\top$ is the *Euler angles* and

$$\mathbf{R}(\boldsymbol{\Theta}) = \begin{bmatrix} c\psi c\theta & -s\psi c\phi + c\psi s\theta s\phi \\ s\psi c\theta & c\psi c\phi + s\phi s\theta s\psi \\ -s\theta & c\theta s\phi \end{bmatrix}$$
$$\begin{bmatrix} s\psi s\phi + c\psi c\phi s\theta \\ -c\psi s\phi + s\theta s\psi c\phi \\ c\theta c\phi \end{bmatrix} \tag{6}$$

with $s\cdot := \sin(\cdot)$, $c\cdot := \cos(\cdot)$ and $t\cdot := \tan(\cdot)$.

The matrix $\mathbf{R}$ is recognized as the Euler angle rotation matrix $\mathbf{R} \in SO(3)$ satisfying $\mathbf{R}\mathbf{R}^\top = \mathbf{R}^\top\mathbf{R} = \mathbf{I}$, and $\det(\mathbf{R}) = 1$, which implies that $\mathbf{R}$ is orthogonal. Consequently, the inverse rotation matrix is given by: $\mathbf{R}^{-1} = \mathbf{R}^\top$. The Euler rates $\dot{\boldsymbol{\Theta}} = T(\boldsymbol{\Theta})\boldsymbol{\omega}$ are singular for $\theta \neq \pm\pi/2$ since:

$$\mathbf{T}(\boldsymbol{\Theta}) = \begin{bmatrix} 1 & s\phi t\theta & c\phi t\theta \\ 0 & c\phi & -s\phi \\ 0 & s\phi/c\theta & c\phi/c\theta \end{bmatrix}, \quad \theta \neq \pm\frac{\pi}{2} \tag{7}$$

Singularities can be avoided by using *unit quaternions* instead (Fossen 1994, 2011).

Kinetics

The rigid-body kinetics can be derived using the *Newton-Euler formulation*, which is based on *Newton's second law.* Following Fossen (1994, 2011) this gives:

$$\mathbf{M}_{RB}\dot{\boldsymbol{v}} + \mathbf{C}_{RB}(\boldsymbol{v})\boldsymbol{v} = \boldsymbol{\tau}_{RB} \tag{8}$$

where $\mathbf{M}_{RB}$ is the rigid-body mass matrix, $\mathbf{C}_{RB}$ is the rigid-body Coriolis and centripetal matrix due to the rotation of $\{b\}$ about the geographical frame $\{n\}$. The generalized force vector $\boldsymbol{\tau}_{RB}$ represents external forces and moments expressed in $\{b\}$. In the nonlinear case:

$$\boldsymbol{\tau}_{RB} = -\mathbf{M}_A\dot{\boldsymbol{v}} - \mathbf{C}_A(\boldsymbol{v})\boldsymbol{v} - \mathbf{D}(\boldsymbol{v})\boldsymbol{v} - \mathbf{g}(\boldsymbol{\eta}) + \boldsymbol{\tau} \tag{9}$$

where the matrices $\mathbf{M}_A$ and $\mathbf{C}_A(\mathbf{v})$ represent hydrodynamic added mass due to acceleration $\dot{\mathbf{v}}$ and Coriolis acceleration due to the rotation of $\{b\}$ about the geographical frame $\{n\}$. The potential and viscous damping terms are lumped together into a nonlinear matrix $\mathbf{D}(\mathbf{v})$ while $\mathbf{g}(\boldsymbol{\eta})$ is a vector of generalized restoring forces. The control inputs are generalized forces given by $\boldsymbol{\tau}$.

Formulae (8) and (9) together with (4) are the fundamental equations when deriving the ship and underwater vehicle models. This is the topic for the next sections.

Ship Model

The ship equations of motion are usually represented in three DOFs by neglecting *heave, roll* and *pitch*. Combining (4), (8), and (9) we get:

$$\dot{\boldsymbol{\eta}} = \mathbf{R}(\psi)\mathbf{v} \qquad (10)$$

$$\mathbf{M}\dot{\mathbf{v}} + \mathbf{C}(\mathbf{v})\mathbf{v} + \mathbf{D}(\mathbf{v})\mathbf{v} = \boldsymbol{\tau} + \boldsymbol{\tau}_{\text{wind}} + \boldsymbol{\tau}_{\text{wave}} \qquad (11)$$

where $\boldsymbol{\eta} := [x, y, \psi]^\top$, $\mathbf{v} := [u, v, r]^\top$ and

$$\mathbf{R}(\psi) = \begin{bmatrix} c\psi & -s\psi & 0 \\ s\psi & c\psi & 0 \\ 0 & 0 & 1 \end{bmatrix} \qquad (12)$$

is the rotation matrix in yaw. It is assumed that wind and wave-induced forces $\boldsymbol{\tau}_{\text{wind}}$ and $\boldsymbol{\tau}_{\text{wave}}$ can be linearly superpositioned. The system matrices $\mathbf{M} = \mathbf{M}_{RB} + \mathbf{M}_A$ and $\mathbf{C}(\mathbf{v}) = \mathbf{C}_{RB}(\mathbf{v}) + \mathbf{C}_A(\mathbf{v})$ are usually derived under the assumption of port-starboard symmetry and that surge can be decoupled from sway and yaw (Fossen 2011). Moreover,

$$\mathbf{M} = \begin{bmatrix} m - X_{\dot{u}} & 0 & 0 \\ 0 & m - Y_{\dot{v}} & mx_g - Y_{\dot{r}} \\ 0 & mx_g - N_{\dot{v}} & I_z - N_{\dot{r}} \end{bmatrix} \qquad (13)$$

$$\mathbf{C}_{RB}(\mathbf{v}) = \begin{bmatrix} 0 & -mr & -mx_g r \\ mr & 0 & 0 \\ mx_g r & 0 & 0 \end{bmatrix} \qquad (14)$$

$$\mathbf{C}_A(\mathbf{v}) = \begin{bmatrix} 0 & 0 & Y_{\dot{v}}v + Y_{\dot{r}}r \\ 0 & 0 & -X_{\dot{u}}u \\ -Y_{\dot{v}}v - Y_{\dot{r}}r & X_{\dot{u}}u & 0 \end{bmatrix} \qquad (15)$$

Hydrodynamic damping will, in its simplest form, be linear:

$$\mathbf{D} = \begin{bmatrix} -X_u & 0 & 0 \\ 0 & -Y_v & -Y_r \\ 0 & -N_r & -N_r \end{bmatrix} \qquad (16)$$

while a nonlinear expression based on second-order modulus functions describing quadratic drag and cross-flow drag is:

$$\mathbf{D}(\mathbf{v}) = \begin{bmatrix} -X_{|u|u}|u| & 0 \\ 0 & -Y_{|v|v}|v| - Y_{|r|v}|r| \\ 0 & -N_{|v|v}|v| - N_{|r|v}|r| \end{bmatrix}$$
$$\begin{matrix} 0 \\ -Y_{|v|r}|v| - Y_{|r|r}|r| \\ -N_{|v|r}|v| - N_{|r|r}|r| \end{matrix} \qquad (17)$$

Other nonlinear representations are found in Fossen (1994, 2011).

In the case of *irrotational ocean currents*, we introduce the relative velocity vector:

$$\mathbf{v}_r = \mathbf{v} - \mathbf{v}_c$$

where $\mathbf{v}_c = [u_c^b, v_c^b, 0]^\top$ is a vector of current velocities in $\{b\}$. Hence, the kinetic model takes the form:

$$\underbrace{\mathbf{M}_{RB}\dot{\mathbf{v}} + \mathbf{C}_{RB}(\mathbf{v})\mathbf{v}}_{\text{rigid-body forces}}$$
$$+ \underbrace{\mathbf{M}_A\dot{\mathbf{v}}_r + \mathbf{C}_A(\mathbf{v}_r)\mathbf{v}_r + \mathbf{D}(\mathbf{v}_r)\mathbf{v}_r}_{\text{hydrodynamic forces}}$$
$$= \boldsymbol{\tau} + \boldsymbol{\tau}_{\text{wind}} + \boldsymbol{\tau}_{\text{wave}}$$

M

This model can be simplified if the *ocean currents* are assumed to be *constant* and *irrotational* in $\{n\}$. According to Fossen (2011, Property 8.1), $\mathbf{M}_{RB}\dot{\boldsymbol{\nu}} + \mathbf{C}_{RB}(\boldsymbol{\nu})\boldsymbol{\nu} \equiv \mathbf{M}_{RB}\dot{\boldsymbol{\nu}}_r + \mathbf{C}_{RB}(\boldsymbol{\nu}_r)\boldsymbol{\nu}_r$ if the rigid-body Coriolis and centripetal matrix satisfies $\mathbf{C}_{RB}(\boldsymbol{\nu}_r) = \mathbf{C}_{RB}(\boldsymbol{\nu})$. One parametrization satisfying this is (14). Hence, the Coriolis and centripetal matrix satisfies $\mathbf{C}(\boldsymbol{\nu}_r) = \mathbf{C}_{RB}(\boldsymbol{\nu}_r) + \mathbf{C}_A(\boldsymbol{\nu}_r)$ and it follows that:

$$\mathbf{M}\dot{\boldsymbol{\nu}}_r + \mathbf{C}(\boldsymbol{\nu}_r)\boldsymbol{\nu}_r + \mathbf{D}(\boldsymbol{\nu}_r)\boldsymbol{\nu}_r = \boldsymbol{\tau} + \boldsymbol{\tau}_{\text{wind}} + \boldsymbol{\tau}_{\text{wave}} \tag{18}$$

The kinematic equation (10) can be modified to include the relative velocity $\boldsymbol{\nu}_r$ according to:

$$\dot{\boldsymbol{\eta}} = \mathbf{R}(\psi)\boldsymbol{\nu}_r + \left[u_c^n, v_c^n, 0\right]^\top \tag{19}$$

where the ocean current velocities $u_c^n = constant$ and $v_c^n = constant$ in $\{n\}$. Notice that the body-fixed velocities $\boldsymbol{\nu}_c = \mathbf{R}(\psi)^\top [u_c^n, v_c^n, 0]^\top$ will vary with the heading angle ψ.

The maneuvering model presented in this entry is intended for controller-observer design, prediction, and computer simulations, as well as system identification and parameter estimation. A large number of application-specific models for marine craft are found in Fossen (2011, Chap. 7).

Hydrodynamic programs compute mass, inertia, potential damping and restoringforces while

a more detailed treatment of viscous dissipative forces (damping) and sealoads are found in the extensive literature on hydrodynamics – see Faltinsen (1990) and Newman (1977).

Underwater Vehicle Model

The 6-DOF underwater vehicle equations of motion follow from (4), (8), and (9) under the assumption that wave-induced motions can be neglected:

$$\dot{\boldsymbol{\eta}} = \mathbf{J}(\boldsymbol{\eta})\boldsymbol{\nu} \tag{20}$$

$$\mathbf{M}\dot{\boldsymbol{\nu}} + \mathbf{C}(\boldsymbol{\nu})\boldsymbol{\nu} + \mathbf{D}(\boldsymbol{\nu})\boldsymbol{\nu} + \mathbf{g}(\boldsymbol{\eta}) = \boldsymbol{\tau} \tag{21}$$

with generalized position $\boldsymbol{\eta} := [x, y, z, \phi, \theta, \psi]^\top$ and velocity $\boldsymbol{\nu} := [u, v, w, p, q, r]^\top$. Assume that the gravitational force acts through the center of gravity (CG) defined by the vector $\mathbf{r}_g := [x_g, y_g, z_g]^\top$ with respect to the coordinate origin $\{b\}$. Similarly, the buoyancy force acts through the center of buoyancy (CB) defined by the vector $\mathbf{r}_b := [x_b, y_b, z_b]^\top$. For most vehicles $y_g = y_b = 0$.

For a port-starboard symmetrical vehicle with homogenous mass distribution, CG satisfying $y_g = 0$ and products of inertia $I_{xy} = I_{yz} = 0$, the system inertia matrix becomes:

$$\mathbf{M} := \begin{bmatrix} m - X_{\dot{u}} & 0 & -X_{\dot{w}} & 0 & mz_g - X_{\dot{q}} & 0 \\ 0 & m - Y_{\dot{v}} & 0 & -mz_g - Y_{\dot{p}} & 0 & mx_g - Y_{\dot{r}} \\ -X_{\dot{w}} & 0 & m - Z_{\dot{w}} & 0 & -mx_g - Z_{\dot{q}} & 0 \\ 0 & -mz_g - Y_{\dot{p}} & 0 & I_x - K_{\dot{p}} & 0 & -I_{zx} - K_{\dot{r}} \\ mz_g - X_{\dot{q}} & 0 & -mx_g - Z_{\dot{q}} & 0 & I_y - M_{\dot{q}} & 0 \\ 0 & mx_g - Y_{\dot{r}} & 0 & -I_{zx} - K_{\dot{r}} & 0 & I_z - N_{\dot{r}} \end{bmatrix} \tag{22}$$

where the hydrodynamic derivatives are defined according to SNAME (1950). The Coriolis and centripetal matrices are:

$$\mathbf{C}_A(\boldsymbol{\nu}) = \begin{bmatrix} 0 & 0 & 0 & 0 & -a_3 & a_2 \\ 0 & 0 & 0 & a_3 & 0 & -a_1 \\ 0 & 0 & 0 & -a_2 & a_1 & 0 \\ 0 & -a_3 & a_2 & 0 & -b_3 & b_2 \\ a_3 & 0 & -a_1 & b_3 & 0 & -b_1 \\ -a_2 & a_1 & 0 & -b_2 & b_1 & 0 \end{bmatrix}$$

(23)

where

$$\begin{aligned} a_1 &= X_{\dot{u}}u + X_{\dot{w}}w + X_{\dot{q}}q \\ a_2 &= Y_{\dot{v}}v + Y_{\dot{p}}p + Y_{\dot{r}}r \\ a_3 &= Z_{\dot{u}}u + Z_{\dot{w}}w + Z_{\dot{q}}q \\ b_1 &= K_{\dot{v}}v + K_{\dot{p}}p + K_{\dot{r}}r \\ b_2 &= M_{\dot{u}}u + M_{\dot{w}}w + M_{\dot{q}}q \\ b_3 &= N_{\dot{v}}v + N_{\dot{p}}p + N_{\dot{r}}r \end{aligned}$$

(24)

and

$$\mathbf{C}_{RB}(\boldsymbol{\nu}) = \begin{bmatrix} 0 & -mr & mq & mz_g r & -mx_g q & -mx_g r \\ mr & 0 & -mp & 0 & m(z_g r + x_g p) & 0 \\ -mq & mp & 0 & -mz_g p & -mz_g q & mx_g p \\ -mz_g r & 0 & mz_g p & 0 & -I_{xz}p + I_z r & -I_y q \\ mx_g q & -m(z_g r + x_g p) & mz_g q & I_{xz}p - I_z r & 0 & -I_{xz}r + I_x p \\ mx_g r & 0 & -mx_g p & I_y q & I_{xz}r - I_x p & 0 \end{bmatrix}$$

(25)

Notice that this representation of $\mathbf{C}_{RB}(\boldsymbol{\nu})$ only depends on the angular velocities p, q, and r, and not the linear velocities $u, v,$ and r. This property will be exploited when including drift due to ocean currents.

Linear damping for a port-starboard symmetrical vehicle takes the following form:

$$\mathbf{D} = - \begin{bmatrix} X_u & 0 & X_w & 0 & X_q & 0 \\ 0 & Y_v & 0 & Y_p & 0 & Y_r \\ Z_u & 0 & Z_w & 0 & Z_q & 0 \\ 0 & K_v & 0 & K_p & 0 & K_r \\ M_u & 0 & M_w & 0 & M_q & 0 \\ 0 & N_v & 0 & N_p & 0 & N_r \end{bmatrix}$$

(26)

Let $W = mg$ and $B = \rho g \nabla$ denote the weight and buoyance where m is the mass of the vehicle including water in free floating space, ∇ the volume of fluid displaced by the vehicle, g the acceleration of gravity (positive downward), and ρ the water density. Hence, the generalized restoring forces for a vehicle satisfying $y_g = y_b = 0$ becomes (Fossen 1994, 2011):

$$\mathbf{g}(\boldsymbol{\eta}) = \begin{bmatrix} (W - B)s\theta \\ -(W - B)c\theta s\phi \\ -(W - B)c\theta c\phi \\ (z_g W - z_b B)c\theta s\phi \\ (z_g W - z_b B)s\theta + (x_g W - x_b B)c\theta c\phi \\ -(x_g W - x_b B)c\theta s\phi \end{bmatrix}$$

(27)

The expression for $\mathbf{D}$ can be extended to include nonlinear damping terms if necessary. Quadratic damping is important at higher speeds since the Coriolis and centripetal terms $\mathbf{C}(\boldsymbol{\nu})\boldsymbol{\nu}$ can destabilize the system if only linear damping is used.

In the presence of irrotational ocean currents, we can rewrite (20) and (21) in terms of relative velocity $\boldsymbol{\nu}_r = \boldsymbol{\nu} - \boldsymbol{\nu}_c$ according to:

$$\dot{\boldsymbol{\eta}} = \mathbf{J}(\boldsymbol{\eta})\boldsymbol{\nu}_r + \left[u_c^n, v_c^n, w_c^n, 0, 0, 0\right]^\top \quad (28)$$

$$\mathbf{M}\dot{\boldsymbol{\nu}}_r + \mathbf{C}(\boldsymbol{\nu}_r)\boldsymbol{\nu}_r + \mathbf{D}(\boldsymbol{\nu}_r)\boldsymbol{\nu}_r + \mathbf{g}(\boldsymbol{\eta}) = \boldsymbol{\tau} \quad (29)$$

where it is assumed that $\mathbf{C}_{RB}(\boldsymbol{\nu}_r) = \mathbf{C}_{RB}(\boldsymbol{\nu})$, which clearly is satisfied for (25). In addition, it is assumed that u_c^n, v_c^n, and w_c^n are constant. For more details see Fossen (2011).

Programs and Data

The Marine Systems Simulator (MSS) is a Matlab/Simulink library and simulator for marine craft (http://www.marinecontrol.org). It includes models for ships, underwater vehicles, and floating structures.

Summary and Future Directions

This entry has presented standard models for simulation of ships and underwater vehicles. It is recommended to consult Fossen (1994, 2011) for a more detailed description of marine craft hydrodynamics.

Mean Field Games

Peter E. Caines
McGill University, Montreal, QC, Canada

Abstract

Mean Field Game (MFG) theory studies the existence of Nash equilibria, together with the individual strategies which generate them, in games involving a large number of agents modeled by controlled stochastic dynamical systems. This is achieved by exploiting the relationship between the finite and corresponding infinite limit population problems. The solution of the infinite population problem is given by the fundamental MFG Hamilton-Jacobi-Bellman (HJB) and Fokker-Planck-Kolmogorov (FPK) equations which are linked by the state distribution of a generic agent, otherwise known as the system's mean field.

Keywords

Fokker-Planck-Kolmogorov (FPK) equation; Hamilton-Jacobi-Bellman (HJB) equation; Nash equilibrium; Stochastic dynamical systems

Introduction

Large-population, dynamical, multi-agent, competitive, and cooperative phenomena occur in a wide range of designed and natural settings such as communication, environmental, epidemiological, transportation, and energy systems, and they underlie much economic and financial behavior. Analysis of such systems is intractable using the finite population game theoretic methods which have been developed for multi-agent control systems (see, e.g., Basar and Ho 1974; Basar and Olsder 1999; Ho 1980; and Bensoussan and Frehse 1984). The continuum population game theoretic models of economics (Aumann and Shapley 1974; Neyman 2002) are static, as, in general, are the large-population models employed in network games (Altman et al. 2002) and transportation analysis (Correa and Stier-Moses 2010; Haurie and Marcotte 1985; Wardrop 1952). However, dynamical (or sequential) stochastic games were analyzed in the continuum limit in the work of Jovanovic and Rosenthal (1988) and Bergin and Bernhardt (1992), where the fundamental mean field equations appear in the form of a discrete time dynamic programming equation and an evolution equation for the population state distribution.

The mean field equations for dynamical games with large but finite populations of asymptotically negligible agents originated in the work of Huang et al. (2003, 2006, 2007) (where the framework was called the Nash Certainty Equivalence Principle) and independently in that of Lasry and Lions (2006a,b, 2007), where the now standard terminology of Mean Field Games (MFGs) was introduced. Independent of both of these, the closely related notion of Oblivious

Equilibria for large-population dynamic games was introduced by Weintraub et al. (2005) in the framework of Markov Decision Processes (MDPs).

One of the main results of MFG theory is that in large-population stochastic dynamic games individual feedback strategies exist for which any given agent will be in a Nash equilibrium with respect to the pre-computable behavior of the mass of the other agents; this holds exactly in the asymptotic limit of an infinite population and with increasing accuracy for a finite population of agents using the infinite population feedback laws as the finite population size tends to infinity, a situation which is termed an ε-Nash equilibrium. This behavior is described by the solution to the infinite population MFG equations which are fundamental to the theory; they consist of (i) a parameterized family of HJB equations (in the nonuniform parameterized agent case) and (ii) a corresponding family of McKean-Vlasov (MV) FPK PDEs, where (i) and (ii) are linked by the probability distribution of the state of a generic agent, that is to say, the mean field. For each agent, these yield (i) a Nash value of the game, (ii) the best response strategy for the agent, (iii) the agent's stochastic differential equation (SDE) (i.e., the MV-SDE pathwise description), and (iv) the state distribution of such an agent (via the MV FPK for the parameterized individual).

Dynamical Agents

In the diffusion-based models of large-population games, the state evolution of a collection of N agents $A_i, 1 \leq i \leq N < \infty$, is specified by a set N of controlled stochastic differential equations (SDEs) which in the important linear case take the form

$$dx_i(t) = [F_i x_i(t) + G_i u_i(t)]dt + D_i dw_i(t),$$
$$1 \leq i \leq N,$$

where $x_i \in \mathbb{R}^n$ is the state, $u_i \in \mathbb{R}^m$ the control input, and w_i the state Wiener process of the ith

agent A_i, where $\{w_i, 1 \leq i \leq N\}$ is a collection of N independent standard Wiener processes in $\mathbb{R}^r$ independent of all mutually independent initial conditions. For simplicity, throughout this entry, all collections of system initial conditions are taken to be independent, zero mean and have finite second moment.

A simplified form of the general case treated in Huang et al. (2007) and Nourian and Caines (2013) is given by the following set of controlled SDEs which for each agent A_i includes state coupling with all other agents:

$$dx_i(t) = \frac{1}{N} \sum_{j=1}^{N} f(t, x_i(t), u_i(t), x_j(t)) dt$$
$$+ \sigma d w_i(t), \quad 1 \leq i \leq N,$$

where here, for the sake of simplicity, only the uniform (non-parameterized) generic agent case is presented. The dynamics of a generic agent in the infinite population limit of this system is then described by the following controlled MV stochastic differential equation:

$$dx(t) = f[t, x(t), u(t), \mu_t] dt + \sigma d w(t),$$

where $f[t, x, u, \mu_t] = \int_{\mathbb{R}^n} f(t, x, u, y) \mu_t(dy)$, with the initial condition measure μ_0 specified, where $\mu_t(\cdot)$ denotes the state distribution of the population at $t \in [0, T]$. The dynamics used in the analysis in Lasry and Lions (2006a,b, 2007) and Cardaliaguet (2012) are of the form $dx_i(t) = u_i(t) dt + \sigma d w_i(t)$.

The dynamical evolution of the state x_i of the ith agent A_i in the discrete time Markov Decision Processes (MDP)-based formulation of the so-called anonymous sequential games (Bergin and Bernhardt 1992; Jovanovic and Rosenthal 1988; Weintraub et al. 2005) is described by a Markov state transition function, or kernel, of the form $P_{t+1} := P(x_i(t+1)|x_i(t), x_{-i}(t), u_i(t), P_t)$.

Agent Performance Functions

In the basic finite population linear-quadratic diffusion case, the agent $A_i, 1 \leq i \leq N$, possesses a performance, or loss, function of the form

$$J_i^N(u_i, u_{-i}) = E \int_0^T \{\|x_i(t) - m_N(t)\|_Q^2 + \|u_i(t)\|_R^2\} dt,$$

where we assume the cost coupling to be of the form $m_N(t) := (\overline{x_N(t)} + \eta)$, $\eta \in \mathbb{R}^n$, where u_{-i} denotes all agents' control laws except for that of the ith agent and $\overline{x_N}$ denotes the population average state $(1/N) \sum_{i=1}^{N} x_i$, and where here and below the expectation is taken over an underlying sample space which carries all initial conditions and Wiener processes.

For the nonlinear case introduced in the previous section, a corresponding finite population mean field loss function is

$$J_i^N(u_i; u_{-i}) :=$$
$$E \int_0^T \left((1/N) \sum_{j=1}^{N} L(t, x_i(t), u_i(t), x_j(t)) \right) dt,$$
$$1 \leq i \leq N,$$

where L is the nonlinear state cost-coupling function. Setting, by possible abuse of notation, $L[t, x, u, \mu_t] = \int_{\mathbb{R}^n} L(t, x, u, y) \mu_t(dy)$, the infinite population limit of this cost function for a generic individual agent A is given by

$$J(u, \mu) := E \int_0^T L[t, x(t), u(t), \mu_t] dt,$$

which is the general expression for the infinite population individual performance functions appearing in Huang et al. (2006) and Nourian and Caines (2013) and which includes those of Lasry and Lions (2006a,b, 2007) and Cardaliaguet (2012). Exponentially discounted costs with discount rate parameter ρ are employed for infinite time horizon performance functions in Huang et al. (2003, 2007), while the sample path

limit of the long-range average is used for ergodic MFG problems in Lasry and Lions (2006a, 2007) and Li and Zhang (2008) and in the analysis of adaptive MFG systems (Kizilkale and Caines 2013).

The Existence of Equilibria

The objective of each agent is to find strategies (i.e., control laws) which are admissible with respect to information and other constraints and which minimize its performance function. The resulting problem is necessarily game theoretic and consequently central results of the topic concern the existence of Nash Equilibria and their properties.

The basic linear-quadratic mean field problem has an explicit solution characterizing a Nash equilibrium (see Huang et al. 2003, 2007). Consider the scalar infinite time horizon discounted case, with nonuniform parameterized agents A_θ with parameter distribution $F(\theta), \theta \in \mathcal{A}$, and dynamical parameters identified as $a_\theta := F_\theta, b_\theta := G_\theta, Q := 1, r := R$; then the so-called Nash Certainty Equivalence (NCE) equation scheme generating the equilibrium solution takes the form

$$\rho s_\theta = \frac{ds_\theta}{dt} + a_\theta s_\theta - \frac{b_\theta^2}{r}\Pi_\theta s_\theta - x^*,$$

$$\frac{d\overline{x}_\theta}{dt} = \left(a_\theta - \frac{b_\theta^2}{r}\Pi_\theta\right)\overline{x}_\theta - \frac{b_\theta^2}{r}s_\theta, \qquad 0 \leq t < \infty,$$

$$\overline{x}(t) = \int_{\mathcal{A}} \overline{x}_\theta(t)dF(\theta),$$

$$x^*(t) = \gamma(\overline{x}(t) + \eta),$$

$$\rho\Pi_\theta = 2a_\theta\Pi_\theta - \frac{b_\theta^2}{r}\Pi_\theta + 1, \quad \Pi_\theta > 0, \qquad \text{Riccati Equation}$$

where the control action of the generic parameterized agent A_θ is given by $u_\theta^0(t) = -\frac{b_\theta}{r}(\Pi_\theta x_\theta(t) + s_\theta(t)), 0 \leq t < \infty$. u_θ^0 is the optimal tracking feedback law with respect to $x^*(t)$ which is an affine function of the mean field term $\overline{x}(t)$, the mean with respect to the parameter distribution F of the $\theta \in \mathcal{A}$ parameterized state means of the agents. Subject to the conditions for the NCE scheme to have a solution, each agent is necessarily in a Nash equilibrium in all full information causal (i.e., non-anticipative) feedback laws with respect to the remainder of the agents when these are employing the law u^0.

It is an important feature of the best response control law u_θ^0 that its form depends only on the parametric data of the entire set of agents, and at any instant it is a feedback function of only the state of the agent A_θ itself and the deterministic mean field-dependent offset s_θ.

For the general nonlinear case, the MFG equations on $[0, T]$ are given by the linked equations for (i) the performance function V for each agent in the continuum, (ii) the FPK for the MV-SDE for that agent, and (iii) the specification of the best response feedback law depending on the mean field measure μ_t and the agent's state $x(t)$. In the uniform agents case, these take the following form.

The Mean Field Game HJB: (MV) FPK Equations

$$[\text{MV-HJB}] \quad -\frac{\partial V(t,x)}{\partial t} = \inf_{u \in U} \left\{ f[t, x(t), u(t), \mu_t] \frac{\partial V(t,x)}{\partial x} + L[t, x(t), u(t), \mu_t] \right\}$$
$$+ \frac{\sigma^2}{2} \frac{\partial^2 V(t,x)}{\partial x^2},$$
$$V(T, x) = 0, \qquad (t, x) \in [0, T] \times \mathbb{R},$$

$$[\text{MV-FPK}] \quad \frac{\partial \mu(t,x)}{\partial t} = -\frac{\partial \{ f[t, x, u(t), \mu_t] \mu(t,x) \}}{\partial x} + \frac{\sigma^2}{2} \frac{\partial^2 \mu(t,x)}{\partial x^2},$$

$$[\text{MV-BR}] \qquad u(t) = \varphi(t, x(t) | \mu_t), \quad (t, x) \in [0, T] \times \mathbb{R}.$$

The general nonlinear MFG problem is approached by different routes in Huang et al. (2006) and Nourian and Caines (2013), and Lasry and Lions (2006a,b, 2007) and Cardaliaguet (2012), respectively. In the former, the so-called probabilistic method solves the MFG equations directly. Subject to technical conditions, an iterated contraction argument establishes the existence of a solution to the HJB-(MV) FPK equations; the best response control laws are obtained from these MFG equations, and these are necessarily Nash equilibria within all causal feedback laws for the infinite population problem. In Lasry and Lions (2006a, 2007) the MFG equations on the infinite time interval (i.e., the ergodic case) are obtained as the limit of Nash equilibria for increasing finite populations, while in the expository notes of Cardaliaguet (2012) the analytic properties of solutions to the HJB-FPK equations on the finite interval are analyzed using PDE methods including the theory of viscosity solutions.

In Huang et al. (2003, 2006, 2007), Nourian and Caines (2013), and Cardaliaguet (2012), it is shown that subject to technical conditions, the solutions to the HJB-FPK scheme yield ε-Nash solutions for finite population MFGs in that for any $\varepsilon > 0$, there exists a population size N_ε such that for all larger populations the use of the feedback law given by the MFG infinite population scheme gives each agent a value to its performance function within ε of the infinite population Nash value.

A counterintuitive feature of these results is that, asymptotically in population size, observations of the states of rival agents are of no value to any given agent; this is in contrast to the situation in single-agent optimal control theory where the value of observations on an agent's environment is in general positive.

Current Developments and Open Problems

There is now an extensive literature on Mean Field Games, the following being a sample: the mathematical literature has focused on the study of general classes of solutions to the fundamental HJB-FPK equations (see e.g., Cardaliaguet (2013)), while in systems and control, the theory of major-minor agent MFG problems (in economics terminology, atoms and continua) is being developed (Huang 2010; Nourian and Caines 2013; Nguyen and Huang 2012), adaptive control extensions of the LQG theory have been carried out (Kizilkale and Caines 2013), and the risk-sensitive case has

been analyzed (Tembine et al. 2012). Much work is now under way in the applications of MFG theory to economics, finance, distributed energy systems, and electrical power markets. Each of these areas has significant open problems, including the application of mathematical transport theory to HJB-FPK equations, the role of MFG theory in portfolio optimization, and the analysis of systems where the presence of partially observed major and minor agent states incurs mean field and agent state estimation.

Mechanism Design

Ramesh Johari
Stanford University, Stanford, CA, USA

Abstract

Mechanism design is concerned with the design of strategic environments to achieve desired outcomes at equilibria of the resulting game. We briefly overview central ideas in mechanism design. We survey both objectives the mechanism designer may seek to achieve, as well as equilibrium concepts the designer may use to model agents. We conclude by discussing a seminal example of mechanism design at work: the Vickrey-Clarke-Groves (VCG) mechanisms.

Keywords

Introduction

Informally, *mechanism design* might be considered "inverse game theory." In mechanism design, a principal (the "designer") creates a system (the "mechanism") in which strategic agents interact with each other. Typically, the goal of the mechanism designer is to ensure that at an "equilibrium" of the resulting strategic interaction, a "desirable" outcome is achieved. Examples of mechanism design at work include the following:

1. The FCC chooses to auction spectrum among multiple competing, strategic bidders to maximize the revenue generated. How should the FCC design the auction?
2. A search engine decides to run a market for sponsored search advertising. How should the market be designed?
3. The local highway authority decides to charge tolls for certain roads to reduce congestion. How should the tolls be chosen?

In each case, the mechanism designer is shaping the incentives of participants in the system. The mechanism designer must first define the desired objective and then choose a mechanism that optimizes that objective given a prediction of how strategic agents will respond. The theory of mechanism design provides guidance in solving such optimization problems.

We provide a brief overview of some central concepts in mechanism design. In the first section, we delve into more detail on the structure of the optimization problem that a mechanism designer solves. In particular, we discuss two central features of this problem: (1) What is the objective that the mechanism designer seeks to achieve or optimize? (2) How does the mechanism designer model the agents, i.e., what equilibrium concept describes their strategic interactions? In the second section, we study a specific celebrated class of mechanisms, the Vickrey-Clarke-Groves mechanisms.

Objectives and Equilibria

A mechanism design problem requires two essential inputs, as described in the introduction. First, what is the objective the mechanism designer is trying to achieve or optimize? And second, what are the constraints within which the mechanism designer operates? On the latter question, perhaps the biggest "constraint" in mechanism design is that the agents are assumed to act rationally in response to whatever mechanism is imposed on them. In other words, the mechanism designer needs to model *how* the agents will interact with each other. Mathematically, this is modeled by a choice of equilibrium concept. For simplicity, we focus only on *static* mechanism design, i.e., mechanism design for settings where all agents act simultaneously.

Objectives

In this section we briefly discuss three objectives the mechanism designer may choose to optimize for: *efficiency*, *revenue*, and a *fairness* criterion.

1. **Efficiency**. When the mechanism designer focuses on "efficiency," they are interested in ensuring that the equilibrium outcome of the game they create is a Pareto efficient outcome. In other words, at an equilibrium of the game, there should be no individual that can be made strictly better off while leaving all others at least as well off as they were before. The most important instantiation of the efficiency criterion arises in *quasilinear* settings, i.e., settings where the utility of all agents is measured in a common, transferable monetary unit. In this case, it can be shown that achieving efficient outcomes is equivalent to maximizing the aggregate utility of all agents in the system. See Chap. 23 in Mas-Colell et al. (1995) for more details on mechanism design for efficient outcomes.

2. **Revenue**. Efficiency may be a reasonable goal for an impartial social planner; on the other hand, in many applied settings, the mechanism designer is often herself a profit-maximizing party. In these cases, it is commonly the goal of the mechanism designer to maximize her own payoff from the mechanism itself.

    A common example of this scenario is in the design of *optimal auctions*. An auction is a mechanism for the sale of a good (or multiple goods) among many competing buyers. When the principal is self-interested, she may wish to choose the auction design that maximizes her revenue from sale; the celebrated paper of Myerson (1981) studies this problem in detail.

3. **Fairness**. Finally, in many settings, the mechanism designer may be interested more in achieving a "fair" outcome – even if such an outcome is potentially not Pareto efficient. Fairness is subjective, and therefore, there are many potential objectives that might be viewed as fair by the mechanism designer. One common setting where the mechanism design strives for fair outcomes is in *cost sharing*: in a canonical example, the cost of a project must be shared "fairly" among many participants. See Chap. 15 of Nisan et al. (2007) for more discussion of such mechanisms.

Equilibrium Concepts

In this section we briefly discuss a range of equilibrium concepts the mechanism designer might use to model the behavior of players. From an optimization viewpoint, mechanism design should be viewed as maximization of the designer's objective, subject to an equilibrium constraint. The equilibrium concept used captures the mechanism designer's judgment about how the agents can be expected to interact with each other, once the mechanism designer has fixed the mechanism. Here we briefly discuss three possible equilibrium concepts that might be used by the mechanism designer.

1. **Dominant strategies**. In dominant strategy implementation, the mechanism designer assumes that agents will play a (weak or strict) dominant strategy against their competitors. This equilibrium concept is obviously quite strong, as dominant strategies may not exist in general. However, the advantage is that when the mechanism possesses dominant strategies for each player, the prediction of play is quite strong. The Vickrey-Clarke-Groves mechanisms described below are central in the theory of mechanism design with dominant strategies.

2. **Bayesian equilibrium**. In a Bayesian equilibrium, agents optimize given a common prior distribution about the other agents' preferences. In Bayesian mechanism design, the mechanism designer chooses a mechanism taking into account that the agents will play according to a Bayesian equilibrium of the resulting game. This solution concept allows the designer to capture a lack of complete information among players, but typically allows for a richer family of mechanisms than mechanism design with dominant strategies. Myerson's work on optimal auction design is carried out in a Bayesian framework (Myerson 1981).

3. **Nash equilibrium**. Finally, in a setting where the mechanism designer believes the agents will be quite knowledgeable about each other's preferences, it may be reasonable to assume they will play a Nash equilibrium of the resulting game. Note that in this case,

it is typically assumed the designer does not know the utilities of agents at the time the mechanism is chosen – even though agents *do* know their own utilities at the time the resulting game is actually played. See, e.g., Moore (1992) for an overview of mechanism design with Nash equilibrium as the solution concept.

The Vickrey-Clarke-Groves Mechanisms

In this section, we describe a seminal example of mechanism design at work: the *Vickrey-Clarke-Groves* (VCG) class of mechanisms. The key insight behind VCG mechanisms is that by structuring payment rules correctly, individuals can be incentivized to truthfully declare their utility functions to the market and in turn achieve an efficient allocation. VCG mechanisms are an example of mechanism design with dominant strategies and with the goal of welfare maximization, i.e., efficiency. The presentation here is based on the material in Chap. 5 of Berry and Johari (2011), and the reader is referred there for further discussion. See also Vickrey (1961), Clarke (1971), and Groves (1973) for the original papers discussing this class of mechanisms.

To illustrate the principle behind VCG mechanisms, consider a simple example where we allocate a single resource of unit capacity among R competing users. Each user's utility is measured in terms of a common currency unit; in particular, if the allocated amount is x_r and the payment to user r is t_r, then her utility is $U_r(x_r) + t_r$; we refer to U_r as the *valuation* function, and let the space of valuation functions be denoted by $\mathcal{U}$. For simplicity we assume the valuation functions are continuous. In line with our discussion of efficiency above, it can be shown that the Pareto efficient allocation is obtained by solving the following:

$$\text{maximize} \quad \sum_r U_r(x_r) \qquad (1)$$

$$\text{subject to} \quad \sum_r x_r \leq 1; \qquad (2)$$

$$\mathbf{x} \geq 0. \qquad (3)$$

However, achieving the efficient allocation requires knowledge of the utility functions; what can we do if these are unknown? The key insight is to make each user act *as if* they are optimizing the aggregate utility, by structuring payments appropriately. The basic approach in a VCG mechanism is to let the strategy space of each user r be the set $\mathcal{U}$ of possible valuation functions and make a payment t_r to user r so that her net payoff has the same form as the social objective (1). In particular, note that if user r receives an allocation x_r and a payment t_r, the payoff to user r is

$$U_r(x_r) + t_r.$$

On the other hand, the social objective (1) can be written as

$$U_r(x_r) + \sum_{s \neq r} U_s(x_s).$$

Comparing the preceding two expressions, the most natural means to align user objectives with the social planner's objectives is to *define the payment t_r as the sum of the valuations of all users other than r.*

A VCG mechanism first asks each user to declare a valuation function. For each r, we use $\hat{U}_r$ to denote the declared valuation function of user r and use $\hat{\mathbf{U}} = (\hat{U}_1, \ldots, \hat{U}_R)$ to denote the vector of declared valuations. Formally, given a vector of declared valuation functions $\hat{\mathbf{U}}$, a VCG mechanism chooses the allocation $\mathbf{x}(\hat{\mathbf{U}})$ as an optimal solution to (1)–(2) given $\hat{\mathbf{U}}$, i.e.,

$$\mathbf{x}(\hat{\mathbf{U}}) \in \arg \max_{\mathbf{x} \geq 0 : \sum_r x_r \leq 1} \sum_r \hat{U}_r(x_r). \qquad (4)$$

The payments are then structured so that

$$t_r(\hat{\mathbf{U}}) = \sum_{s \neq r} \hat{U}_s(x_s(\hat{\mathbf{U}})) + h_r(\hat{\mathbf{U}}_{-r}). \qquad (5)$$

Here h_r is an arbitrary function of the declared valuation functions of users other than r, and various definitions of h_r give rise to variants of the VCG mechanisms. Since user r cannot affect this term through the choice of $\hat{U}_r$, she chooses $\hat{U}_r$ to maximize

$$U_r(x_r(\hat{\mathbf{U}})) + \sum_{s \neq r} \hat{U}_s(x_s(\hat{\mathbf{U}})).$$

Now note that given $\hat{\mathbf{U}}_{-r}$, the above expression is bounded above by

$$\max_{\mathbf{x} \geq 0: \sum_r x_r \leq 1} \left[U_r(x_r) + \sum_{s \neq r} \hat{U}_s(x_s) \right].$$

But since $\mathbf{x}(\hat{\mathbf{U}})$ satisfies (4), user r can achieve the preceding maximum by truthfully declaring $\hat{U}_r = U_r$. Since this optimal strategy does not depend on the valuation functions $(\hat{U}_s, s \neq r)$ declared by the other users, we recover the important fact that in a VCG mechanism, *truthful declaration is a weak dominant strategy for user r*.

For our purposes, the interesting feature of the VCG mechanism is that it elicits the true utilities from the users and in turn (because of the definition of $\mathbf{x}(\hat{\mathbf{U}})$) chooses an efficient allocation. The feature that truthfulness is a dominant strategy is known as *incentive compatibility*: the individual incentives of users are aligned, or "compatible," with overall efficiency of the system. The VCG mechanism achieves this by effectively paying each agent to tell the truth. The significance of the approach is that this payment can be properly structured even if the resource manager does not have prior knowledge of the true valuation functions.

Summary and Future Directions

Mechanism design provides an overarching framework for the "engineering" of economic systems. However, many significant challenges remain. First, VCG mechanisms are not computationally tractable in complex settings, e.g., combinatorial auctions (Hajek 2013); finding computationally tractable yet efficient mechanisms is a very active area of current research. Second, VCG mechanisms optimize for overall welfare, rather than revenue, and finding simple mechanisms that maximize revenue also presents new challenges. Finally,

we have only considered implementation in static environments. Most practical mechanism design settings are dynamic. Dynamic mechanism design remains an active area of fruitful research.

Model Building for Control System Synthesis

Marco Lovera and Francesco Casella
Politecnico di Milano, Milan, Italy

Abstract

The process of developing control-oriented mathematical models of physical systems is a complex task, which in general implies a careful combination of prior knowledge about the physics of

the system under study with information coming from experimental data. In this article the role of mathematical models in control system design and the problem of developing compact control-oriented models are discussed.

Keywords

Analytical models; Computational modeling; Continuous-time systems; Control-oriented modeling; Discrete-time systems; Parameter-varying systems; Simulation; System identification; Time-invariant systems; Time-varying systems; Uncertainty

Introduction

The design of automatic control systems requires the availability of some knowledge of the dynamics of the process to be controlled. In this respect, current methods for control system synthesis can be classified in two broad categories: model-free and model-based ones.

The former aim at designing (or tuning) controllers solely on the basis of experimental data collected directly on the plant, without resorting to mathematical models.

The latter, on the contrary, assume that suitable models of the plant to be controlled are available, and rely on this information to work out control laws capable of meeting the design requirements.

While the research on model-free design methods is a very active field, the vast majority of control synthesis methods and tools fall in the model-based category and therefore assume that knowledge about the plant to be controlled is encoded in the form of dynamic models of the plant itself. Furthermore, in an increasing number of application areas, control system performance is becoming a key competitive factor for the success of innovative, high-tech systems. Consider, for example, high-performance mechatronic systems (such as robots); vehicles enhanced by active integrated stability, suspension, and braking control;

aerospace systems; advanced energy conversion systems. All the abovementioned applications possess at least one of the following features, which in turn call for accurate mathematical modeling for the design of the control system: closed-loop performance critically depends on the dynamic behavior of the plant; the system is made of many closely interacting subsystems; advanced control systems are required to obtain competitive performance, and these in turn depend on explicit mathematical models for their design; the system is safety critical and requires extensive validation of closed-loop stability and performance by simulation.

Therefore, building control-oriented mathematical models of physical systems is a crucial prerequisite to the design process itself (see, e.g., Lovera (2014) for a more detailed treatment of this topic).

In the following, two aspects related to modeling for control system synthesis will be discussed, namely, the role of models for control system synthesis and the actual process of model building itself.

The Role of Models for Control System Synthesis

Mathematical models play a number of different roles in the design of control systems. In particular, different classes of mathematical models are usually employed: *detailed*, high-fidelity models for system simulation and *compact* models for control design. In this section the two model classes are presented and their respective roles in the design of control systems are described. Note, in passing, that although hybrid system control is an interesting and emerging field, this entry will focus on purely continuous-time physical models, with application to the design of continuous-time or sampled-time control systems.

Detailed Models for System Simulation
Detailed models play a double role in the control design process. On one hand, they allow checking how good (or crude) the compact model is, compared to a more detailed description, thus helping

to develop good compact models. On the other hand, they allow closed-loop performance verification of the controlled system, once a controller design is available. Indeed, verifying closed-loop performance using the same simplified model that was used for control system design is not a sound practice; conversely, verification performed with a more detailed model is usually deemed a good indicator of the control system performance, whenever experimental validation is not possible for some reason.

Object-oriented modeling (OOM) methodologies and equation-based, object-oriented languages (EOOLs) provide very good support for the development of such high-fidelity models, thanks to equation-based modeling, acausal physical ports, hierarchical system composition, and inheritance; see Tiller (2001) for a comprehensive overview. Any continuous-time EOOL model is equivalent to the set of differential-algebraic equations (DAEs)

$$F(x(t), \dot{x}(t), u(t), y(t), p, t) = 0, \quad (1)$$

where x is the vector of dynamic variables, u is the vector of input variables, y is the vector of algebraic variables, p is the vector of parameters and t is the time. It is interesting to highlight that the object-oriented approach (in particular, the use of replaceable components) allows defining and managing families of models of the same plant with different levels of complexity, by providing more or less detailed implementations of the same abstract interfaces. This feature of OOM allows the development of simulation models for different purposes and with different degrees of detail throughout the entire life of an engineering project, from preliminary design down to commissioning and personnel training, all within a coherent framework.

In particular, when focusing on control systems verification (and regardless of the actual control design methodology) once the controller has been set up, an OOM tool can be used to run closed-loop simulations, including both the plant and the controller model. Many OOM tools provide model export facilities, which allow to connect a plant model with only causal external connectors (actuator inputs and sensor outputs) to a causal controller model in a causal simulation environment. From a mathematical point of view, this corresponds to reformulating (1) in state-space form, by means of analytical and/or numerical transformations.

Finally, it is important to point out that physical model descriptions based on partial-differential equations (PDEs) can be handled in the OOM framework by means of discretization using finite volume, finite elements, or finite differences methods.

Compact Models for Control Design

The requirements for a control-oriented model can vary significantly from application to application. Design models can be tentatively classified in terms of two key features: complexity and accuracy. For a dynamic model, complexity can be measured in terms of its order; accuracy, on the other hand, can be measured using many different metrics (e.g., time-domain simulation or prediction error, frequency domain matching with the real plant, etc.) related to the capability of the model to reproduce the behavior of the true system in the operating conditions of interest.

Broadly speaking, it can be safely stated that the required level of closed-loop performance drives the requirements on the accuracy and complexity of the design model. Similarly, it is intuitive that more complex models have the potential for being more accurate. So, one might be tempted to resort to very detailed mathematical representations of the plant to be controlled in order to maximize closed-loop performance. This consideration however is moderated by a number of additional requirements, which actually end up driving the control-oriented modeling process. First of all, present-day controller synthesis methods and tools have computational limitations in terms of the complexity of the mathematical models they can handle, so compact models representative of the dominant dynamics of the system under study are what is really needed. Furthermore, for many synthesis methods (such as, e.g., LQG or H_∞ synthesis), the complexity of the design model has an impact on the complexity of the controller,

which in turn is constrained by implementation issues. Last but not least, in engineering projects, the budget of the control-oriented modeling activity is usually quite limited, so the achievable level of accuracy is affected by this limitation.

It is clear from the above discussion that developing mathematical models suitable for control system synthesis is a nontrivial task but rather corresponds to the pursuit of a careful tradeoff between complexity and accuracy. Furthermore, throughout the model development, one should keep in mind the eventual control application of the model, so its mathematical structure has to be compatible with currently available methods and tools for control system analysis and design.

Control-oriented models are usually formulated in state-space form:

$$\begin{aligned} \dot{x}(t) &= f(x(t), u(t), p, t) \\ y(t) &= g(x(t), u(t), p, t) \end{aligned} \quad (2)$$

where x is the vector of state variables, u is the vector of system inputs (control variables and disturbances), y is the vector of system outputs, p is the vector of parameters, and t is the continuous time. In the following, however, the focus will be on linear models, which constitute the starting point for most control law design methods and tools. In this respect, the main categories of models used in control system synthesis can be defined as follows.

Linear Time-Invariant Models

Linear time-invariant (LTI) models can be described in state-space form as

$$\begin{aligned} \dot{x}(t) &= Ax(t) + Bu(t) \\ y(t) &= Cx(t) + Du(t) \end{aligned} \quad (3)$$

or, equivalently, using an input-output model given by the (rational) transfer function

$$G(s) = C(sI - A)^{-1}B + D, \quad (4)$$

where s denotes the Laplace variable. In many cases, the dynamics of systems in the form (2) in the neighborhood of an equilibrium (trim) point

is approximated by (3) via analytical or numerical linearization.

If, on the contrary, the control-oriented model is obtained by linearization of the DAE system (1), then a generalized LTI (or descriptor) model in the form

$$\begin{aligned} E\dot{x}(t) &= Ax(t) + Bu(t) \\ y(t) &= Cx(t) + Du(t) \end{aligned} \quad (5)$$

is obtained. Clearly, a generalized LTI model is equivalent to a conventional one as long as E is nonsingular. The generalized form, however, encompasses the wider class of linearized plants with a singular E.

Linear Time-Varying Models

In some engineering applications, the need may arise to linearize the detailed model in the neighborhood of a trajectory rather than around an equilibrium point. Whenever this is the case, a linear time-varying (LTV) model is obtained, in the form

$$\begin{aligned} \dot{x}(t) &= A(t)x(t) + B(t)u(t) \\ y(t) &= C(t)x(t) + D(t)u(t). \end{aligned} \quad (6)$$

An important subclass is the one of time periodic behavior of the state-space matrices of the model, which corresponds to a linear time periodic (LTP) model. LTP models arise when considering the linearization along periodic trajectories or, as it occurs in a number of engineering problems, whenever rotating systems are considered (e.g., spacecraft, rotorcraft, wind turbines). Finally, it is interesting to recall that (discrete-time) LTP models are needed to model multi-rate sampled data systems.

Linear Parameter-Varying models

The control-oriented modeling problem can be also formulated as the one of *simultaneously* representing all the linearizations of interest for control purposes of a given nonlinear plant. Indeed, in many control engineering applications a single control system must be designed to guarantee the satisfactory closed-loop operation of a given plant in many different operating

conditions (either equilibria or trajectories). Many design techniques are now available for this problem (see, e.g., Mohammadpour and Scherer 2012), provided that a suitable model in parameter-dependent form has been derived for the system to be controlled. Linear parameter-varying (LPV) models, described in state-space form as

$$\begin{aligned} \dot{x}(t) &= A(p(t))x(t) + B(p(t))u(t) \\ y(t) &= C(p(t))x(t) + D(p(t))u(t) \end{aligned} \quad (7)$$

are linear models the state-space representation of which depends on a parameter vector p that can be time varying. The elements of vector p may or may not be measurable, depending on the specific problem formulation. The present state of the art of LPV modeling can be briefly summarized by defining two classes of approaches (see Lopes dos Santos et al. (2011) for details). *Analytical* methods based on the availability of reliable nonlinear equations for the dynamics of the plant, from which suitable control-oriented representations can be derived (by resorting to, broadly speaking, suitable extensions of the familiar notion of linearization, developed in order to take into account off-equilibrium operation of the system). *Experimental* methods based entirely on identification, i.e., aimed at deriving LPV models for the plant directly from input/output data. In particular, some LPV identification techniques assume that one *global* identification experiment in which both the control input and the parameter vector are (persistently) excited in a simultaneous way, while others aim at deriving a parameter-dependent model on the basis of *local* experiments only, i.e., experiments in which the parameter vector is held constant and only the control input is excited.

Modern control theory provides methods and tools to deal with design problems in which stability and performance have to be guaranteed also in the presence of model uncertainty, both for regulation around a specified operating point and for gain scheduled control system design. Therefore, modeling for control system synthesis should also provide methods to account for model uncertainty (both parametric and nonparametric) in the considered model class.

Most of the existing control design literature assumes that the plant model is given in the form of a linear fractional transformation (LFT) (see, e.g., Skogestad and Postlethwaite (2007) for an introduction to LFT modeling of uncertainty and Hecker et al. (2005) for a discussion of algorithms and software tools). LFT models consist of a feedback interconnection between a *nominal* LTI plant and a (usually norm-bounded) operator which represents model uncertainties, e.g., poorly known or time-varying parameters, nonlinearities, etc. A generic such LFT interconnection is depicted in Fig. 1, where the nominal plant is denoted with P and the uncertainty block is denoted with Δ. The LFT formalism can be also used to provide a structured representation for the state-space form of LPV models, as depicted in Fig. 2, where the block $\Delta(\alpha)$ takes into account the presence of the uncertain parameter vector α, while the block $\Delta(p)$ models the effect of the varying operating point, parameterized by the vector of time-varying parameters p. Therefore, LFT models can be used for the design of robust and gain scheduling controllers; in addition they can also serve as a basis for structured model identification techniques, where the uncertain parameters that appear in the feedback blocks are estimated based on input/output data sequences. The process of extracting uncertain/scheduling parameters from the design model of the system
Model Building for Control System Synthesis, Fig. 1 Block diagram of the typical LFT interconnection adopted in the robust control framework
Model Building for Control System Synthesis, Fig. 2 Block diagram of the typical LFT interconnection adopted in the robust LPV control framework

to be controlled is a highly complex one, in which symbolic techniques play a very important role. Tools already exist to perform this task (see, e.g., Hecker et al. 2005), while a recent overview of the state of the art in this research area can be found in Hecker and Varga (2006).

Finally, it is important to point out that there is a vast body of advanced control techniques which are based on discrete-time models:

$$x(k + 1) = f(x(k), u(k), p, k)$$
$$y(k) = g(x(k), u(k), p, k) \qquad (8)$$

where the integer time step k usually corresponds to multiples of a sampling period T_s. Many techniques are available to transform (2) into (8). Furthermore, LTI, LTV, and LPV models can be formulated in discrete time rather than in continuous time.

Building Models for Control System Synthesis

The development of control-oriented models of physical systems is a complex task, which in general implies a careful combination of prior knowledge about the physics of the system under study with information coming from experimental data. In particular, this process can follow very different paths depending on the type of information which is available on the plant to be controlled. Such paths are typically classified in the literature as follows (see, e.g., Ljung (2008) for a more detailed discussion).

White box modeling refers to the development of control-oriented models on the basis of first principles only. In this framework, one uses the available information on the plant to develop a detailed model using OOM or EOOL tools and subsequently works out a compact control-oriented model from it. If the adopted tool only supports simulation, then one can run simulations of the plant model, subject to suitably chosen excitation inputs (ranging from steps to persistently exciting input sequences such as, e.g., pseudorandom binary sequences and sine

sweeps) and then reconstruct the dynamics by means of system identification methods. Note that in this way the structure/order selection stage of the system identification process provides effective means to manage the complexity versus accuracy tradeoff in the derivation of the compact model. A more direct approach, presently supported by many tools, is to directly compute the A, B, C, D matrices of the linearized system around specified equilibrium (trim) points, using symbolic and/or numerical linearization techniques. The result is usually a high-order linear system, which then can (sometimes must) be reduced to a low-order system by using model order reduction techniques (such as, e.g., balanced truncation). Model reduction techniques (see Antoulas (2009) for an in-depth treatment of this topic) allow to automatically obtain approximated compact models such as (3), starting from much more detailed simulation models, by formulating specific approximation bounds in control-relevant terms (e.g., percentage errors of steady-state output values, norm-bounded additive or multiplicative errors of weighted transfer functions, or L_2-norm errors of output transients in response to specified input signals).

Black box modeling, on the other hand, corresponds to situations in which the modeling activity is entirely based on input-output data collected on the plant (which therefore must be already available), possibly in dedicated, suitably designed, experiments (see Ljung 1999). Regardless of the type of model to be built (i.e., linear or nonlinear, time invariant or time varying, discrete time or continuous time), the black box approach consists of a number of well-defined steps. First of all the structure of the model to be identified must be defined: in the linear time-invariant case, this corresponds to the choice of the number of poles and zeros for an input-output model or to the choice of model order for a state-space representation; in the nonlinear case structure selection is a much more involved process in view of the much larger number of degrees of freedom which are potentially involved. Once a model structure has been defined, a suitable

cost function to measure the model performance must be selected (e.g., time-domain simulation or prediction error, frequency domain model fitting, etc.) and the experiments to collect identification and validation data must be designed. Finally, the uncertain model parameters must be estimated from the available identification dataset and the model must be validated on the validation dataset.

Grey box modeling (in various shades) corresponds to the many possible intermediate cases which can occur in practice, ranging from the white box approach to the black box one. As recently discussed in Ljung (2008), the critical issue in the development of an effective approach to control-oriented grey box modeling lies in the integration of existing methods and tools for physical systems modeling and simulation with methods and tools for parameter estimation. Such integration can take place in a number of different ways depending on the relative role of data and priors on the physics of the system in the specific application. A typical situation which occurs frequently in applications is when a white box model (developed by means of OOM or EOOL tools) contains parameters having unknown or uncertain numerical values (such as, e.g., damping factors in structural models, aerodynamic coefficients in aircraft models and so on). Then, one may rely on input-output data collected in dedicated experiments on the real system to refine the white box model by estimating the parameters using the information provided by the data. This process is typically dependent on the specific application domain as the type of experiment, the number of measurements, and the estimation technique must meet application-specific constraints (see, e.g., Klein and Morelli (2006) for an overview of grey box modeling in aerospace applications).

Summary and Future Directions

In this article the problem of model building for control system synthesis has been considered. An overview of the different uses of mathematical models in control system design has been provided and the process of building compact control-oriented models starting from prior knowledge about the system and/or experimental data has been discussed. Present-day modeling and simulation tools support advanced control system design in a much more direct way. In particular, while methods and tools for the individual steps in the modeling process (such as OOM, linearization and model reduction, parameter estimation) are available, an integrated environment enabling the pursuit of all the abovementioned paths to the development of compact control-oriented models is still a subject for future development. The availability of such a tool might further promote the application of advanced, model-based techniques that are currently limited by the model development process.

Model Order Reduction: Techniques and Tools

Peter Benner[1] and Heike Faßbender[2]
[1]Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg, Germany
[2]Institut Computational Mathematics, Technische Universität Braunschweig, Braunschweig, Germany

Abstract

Model order reduction (MOR) is here understood as a computational technique to reduce the order of a dynamical system described by a set of ordinary or differential-algebraic equations (ODEs or DAEs) to facilitate or enable its simulation, the design of a controller, or optimization and design of the physical system modeled. It focuses on representing the map from inputs into the system to its outputs, while its dynamics are treated as a black box so that the large-scale set of describing ODEs/DAEs can be replaced by a much smaller set of ODEs/DAEs without sacrificing the accuracy of the input-to-output behavior.

Keywords

Problem Description

This survey is concerned with linear time-invariant (LTI) systems in state-space form

$$\begin{aligned} E\dot{x}(t) &= Ax(t) + Bu(t), \\ y(t) &= Cx(t) + Du(t), \end{aligned} \tag{1}$$

where $E, A \in \mathbb{R}^{n \times n}$ are the system matrices, $B \in \mathbb{R}^{n \times m}$ is the input matrix, $C \in \mathbb{R}^{p \times n}$ is the output matrix, and $D \in \mathbb{R}^{p \times m}$ is the feedthrough (or input–output) matrix. The size n of the matrix A is often referred to as the order of the LTI system. It mainly determines the amount of time needed to simulate the LTI system.

Such LTI systems often arise from a finite element modeling using commercial software such as ANSYS or NASTRAN which results in a second-order differential equation of the form

$$\begin{aligned} M\ddot{x}(t) + D\dot{x}(t) + Kx(t) &= Fu(t), \\ y(t) &= C_p x(t) + C_v \dot{x}(t), \end{aligned}$$

where the mass matrix M, the stiffness matrix K, and the damping matrix D are square matrices in $\mathbb{R}^{s \times s}$, $F \in \mathbb{R}^{s \times m}$, $C_p, C_v \in \mathbb{R}^{q \times s}$, $x(t) \in \mathbb{R}^s$, $u(t) \in \mathbb{R}^m$, $y(t) \in \mathbb{R}^q$. Such second-order differential equations are typically transformed to a mathematically equivalent first-order differential equation

$$\underbrace{\begin{bmatrix} I & 0 \\ 0 & M \end{bmatrix}}_{E} \underbrace{\begin{bmatrix} \dot{x}(t) \\ \ddot{x}(t) \end{bmatrix}}_{\dot{z}(t)} = \underbrace{\begin{bmatrix} 0 & I \\ -K & -D \end{bmatrix}}_{A} \underbrace{\begin{bmatrix} x(t) \\ \dot{x}(t) \end{bmatrix}}_{z(t)} + \underbrace{\begin{bmatrix} 0 \\ F \end{bmatrix}}_{B} u(t)$$

$$y(t) = \underbrace{\begin{bmatrix} C_p & C_v \end{bmatrix}}_{C} \underbrace{\begin{bmatrix} x(t) \\ \dot{x}(t) \end{bmatrix}}_{z(t)},$$

where $E, A \in \mathbb{R}^{2s \times 2s}$, $B \in \mathbb{R}^{2s \times m}$, $C \in \mathbb{R}^{q \times 2s}$, $z(t) \in \mathbb{R}^{2s}$, $u(t) \in \mathbb{R}^m$, $y(t) \in \mathbb{R}^q$. Various other linearizations have been proposed in the literature.

The matrix E may be singular. In that case the first equation in (1) defines a system of differential-algebraic equations (DAEs); otherwise it is a system of ordinary differential equations (ODEs). For example, for $E = \begin{bmatrix} J & 0 \\ 0 & 0 \end{bmatrix}$ with a $j \times j$ nonsingular matrix J, only the first j equations in the left-hand side expression in (1) form ordinary differential equations, while the last $n - j$ equations form homogeneous linear equations. If further $A = \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix}$ and $B = \begin{bmatrix} B_1 \\ B_2 \end{bmatrix}$ with the $j \times j$ matrix A_{11}, the $j \times m$ matrix B_1 and a nonsingular matrix A_{22}, this is easily seen: partitioning the state vector $x(t) = \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix}$ with $x_1(t)$ of length j, the DAE $E\dot{x}(t) = Ax(t) + Bu(t)$ splits into the algebraic equation $0 = A_{22}x_2(t) + B_2u_2(t)$, and the ODE

$$J\dot{x}_1(t) = A_{11}x_1(t) + \left(B_1 - A_{12}A_{22}^{-1}B_2 \right) u(t).$$

To simplify the description, only continuous-time systems are considered here. The discrete-time case can be treated mostly analogously; see, e.g., Antoulas (2005).

An alternative way to represent LTI systems is provided by the transfer function matrix (TFM), a matrix-valued function whose elements are rational functions. Assuming $x(0) = 0$ and taking Laplace transforms in (1) yields $sX(s) = AX(s) + BU(s)$, $Y(s) = CX(s) + DU(s)$, where $X(s)$, $Y(s)$, and $U(s)$ are the Laplace transforms of the time signals $x(t)$, $y(t)$ and $u(t)$, respectively. The map from inputs U to outputs Y is then described by $Y(s) = G(s)U(s)$ with the TFM

$$G(s) = C(sE - A)^{-1}B + D, \qquad s \in \mathbb{C}. \quad (2)$$

The aim of model order reduction is to find an LTI system

$$\widetilde{E}\dot{\tilde{x}}(t) = \widetilde{A}\tilde{x}(t) + \widetilde{B}u(t), \;\; \tilde{y}(t) = \widetilde{C}\tilde{x}(t) + \widetilde{D}u(t) \quad (3)$$

of reduced-order $r \ll n$ such that the corresponding TFM

$$\widetilde{G}(s) = \widetilde{C}(s\widetilde{E} - \widetilde{A})^{-1}\widetilde{B} + \widetilde{D} \quad (4)$$

approximates the original TFM (2). That is, using the same input $u(t)$ in (1) and (3), we want that the output $\tilde{y}(t)$ of the reduced order model (ROM) (3) approximates the output $y(t)$ of (1) well enough for the application considered (e.g., controller design). In general, one requires $\|y(t) - \tilde{y}(t)\| \leq \varepsilon$ for all feasible inputs $u(t)$, for (almost) all t in the time domain of interest, and for a suitable norm $\| \cdot \|$. In control theory one often employs the $\mathcal{L}_2$- or $\mathcal{L}_\infty$-norms on $\mathbb{R}$ or $[0, \infty]$, respectively, to measure time signals or their Laplace transforms. In the situations considered here, the $\mathcal{L}_2$-norms employed in frequency and time domain coincide due to the Paley-Wiener theorem (or Parseval's equation or the Plancherel theorem, respectively); see Antoulas (2005) and Zhou et al. (1996) for details. As $Y(s) - \widetilde{Y}(s) = (G(s) - \widetilde{G}(s))U(s)$, one can therefore consider the approximation error of the TFM $\|G(\cdot) - \widetilde{G}(\cdot)\|$ measured in an induced norm instead of the error in the output $\|y(\cdot) - \tilde{y}(\cdot)\|$.

Depending on the choice of the norm, different MOR goals can be formulated. Typical choices are (see, e.g., Antoulas (2005) for a more thorough discussion)

• $\|G(\cdot) - \widetilde{G}(\cdot)\|_{\mathcal{H}_\infty}$, where

$$\|F(.)\|_{\mathcal{H}_\infty} = \sup_{s \in \mathbb{C}_+} \sigma_{\max}(F(s)).$$

Here, $\sigma_{\max}$ is the largest singular value of the matrix $F(s)$. This minimizes the maximal magnitude of the frequency response of the error system and by the Paley-Wiener theorem bounds the $\mathcal{L}_2$-norm of the output error.

• $\|G(\cdot) - \widetilde{G}(\cdot)\|_{\mathcal{H}_2}$, where (with $\iota = \sqrt{-1}$)

$$\|F(\cdot)\|_{\mathcal{H}_2}^2 = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \mathrm{tr}\left(F(\iota\omega)^* F(\iota\omega) \right) d\omega.$$

This ensures a small error $\|y(\cdot) - \tilde{y}(\cdot)\|_{\mathcal{L}_\infty(0,\infty)} = \sup_{t>0} \|y(t) - \tilde{y}(t)\|_\infty$ (with $\| . \|_\infty$ denoting the maximum norm of a vector)

uniformly over all inputs $u(t)$ having bounded $\mathcal{L}_2$-energy, that is, $\int_0^\infty u(t)^T u(t) dt \leq 1$; see Gugercin et al. (2008).

Besides a small approximation error, one may impose additional constraints for the ROM. One might require certain properties (such as stability and passivity) of the original systems to be preserved. Rather than considering the full nonnegative real line in time domain or the full imaginary axis in frequency domain, one can also consider bounded intervals in both domains. For these variants, see, e.g., Antoulas (2005) and Obinata and Anderson (2001).

Methods

There are a number of different methods to construct ROMs, see, e.g., Antoulas (2005), Benner et al. (2005), Obinata and Anderson (2001), and Schilders et al. (2008). Here we concentrate on projection-based methods which restrict the full state $x(t)$ to an r-dimensional subspace by choosing $\tilde{x}(t) = W^* x(t)$, where W is an $n \times r$ matrix. Here the conjugate transpose of a complex-valued matrix Z is denoted by Z^*, while the transpose of a matrix Y will be denoted by Y^T. Choosing $V \in \mathbb{C}^{n \times r}$ such that $W^* V = I \in \mathbb{R}^{r \times r}$ yields an $n \times n$ projection matrix $\Pi = V W^*$ which projects onto the r-dimensional subspace spanned by the columns of V along the kernel of W^*. Applying this projection to (1), one obtains the reduced-order LTI system (3) with

$$\widetilde{E} = W^* E V, \ \tilde{A} = W^* A V, \ \widetilde{B} = W^* B, \ \widetilde{C} = C V \tag{5}$$

and an unchanged $\widetilde{D} = D$. If $V = W$, Π is an orthogonal projector and is called a Galerkin projection. If $V \neq W$, Π is an oblique projector, sometimes called a Petrov-Galerkin projection.

In the following, we will briefly discuss the main classes of methods to construct suitable matrices V and W: truncation-based methods and interpolation-based methods. Other methods, in particular combinations of the two classes discussed here, can be found in the literature. In case the original LTI system is real, it is often desirable

to construct a real reduced-order model. All of the methods discussed in the following either do construct a real reduced-order system or there is a variant of the method which does. In order to keep this exposition at a reasonable length, the reader is referred to the cited literature.

Truncation Based Methods

The general idea of truncation is most easily explained by *modal truncation*: For simplicity, assume that $E = I$ and that A is diagonalizable, $T^{-1} A T = D_A = \text{diag}(\lambda_1, \ldots, \lambda_n)$. Further we assume that the eigenvalues $\lambda_\ell \in \mathbb{C}$ of A can be ordered such that

$$\text{Re}(\lambda_n) \leq \text{Re}(\lambda_{n-1}) \leq \ldots \leq \text{Re}(\lambda_1) < 0, \tag{6}$$

(i.e., all eigenvalues lie in the open left half complex plane). This implies that the system is stable. Let V be the $n \times r$ matrix consisting of the first r columns of T and let W^* be the first r rows of T^{-1}, that is, $W = V(V^* V)^{-1}$. Applying the transformation T to the LTI system (1) yields

$$T^{-1} \dot{x}(t) = (T^{-1} A T) T^{-1} x(t) + (T^{-1} B) u(t) \tag{7}$$

$$y(t) = (C T) T^{-1} x(t) + D u(t) \tag{8}$$

with

$$T^{-1} A T = \begin{bmatrix} W^* A V & \\ & A_2 \end{bmatrix}, \ T^{-1} B = \begin{bmatrix} W^* B \\ B_2 \end{bmatrix},$$

and $C T = [C V \ C_2]$, where $W^* A V = \text{diag}(\lambda_1, \ldots, \lambda_r)$ and $A_2 = \text{diag}(\lambda_{r+1}, \ldots, \lambda_n)$. Preserving the r dominant poles (eigenvalues with largest real part) by truncating the rest (i.e., discarding A_2, B_2, and C_2 from (7)) yields the ROM as in (5). It can be shown that the error bound

$$\|G(\cdot) - \widetilde{G}(\cdot)\|_{\mathcal{H}_\infty} \leq \|C_2\| \ \|B_2\| \frac{1}{|\text{Re}(\lambda_{r+1})|}$$

holds (Benner 2006). As eigenvalues contain only limited information about the system, this is not necessarily a meaningful reduced-order system. In particular, the dependence of the input–output relation on B and C is completely ignored.

This can be enhanced by more refined dominance measures taking B and C into account; see, e.g., Varga (1995) and Benner et al. (2011).

More suitable reduced-order systems can be obtained by *balanced truncation*. To introduce this concept, we no longer need to assume A to be diagonalizable, but we require the stability of A in the sense of (6). For simplicity, we assume $E = I$. For treatment of the DAE case ($E \neq I$), see Benner et al. (2005, Chap. 3). Loosely speaking, a balanced representation of an LTI system is obtained by a change of coordinates such that the states which are hard to reach are at the same time those which are difficult to observe. This change of coordinates amounts to an equivalence transformation of the realization (A, B, C, D) of (1) called state-space transformation as in (7), where T now is the matrix representing the change of coordinates. The new system matrices $(T^{-1}AT, T^{-1}B, CT, D)$ form a balanced realization of (1). Truncating in this balanced realization the states that are hard to reach and difficult to observe results in a ROM.

Consider the Lyapunov equations

$$AP + PA^T + BB^T = 0, \ \ A^T Q + QA + C^T C = 0. \tag{9}$$

The solution matrices P and Q are called controllability and observability Gramians, respectively. If both Gramians are positive definite, the LTI system is minimal. This will be assumed from here on in this section.

In balanced coordinates the Gramians P and Q of a stable minimal LTI system satisfy $P = Q = \mathrm{diag}(\sigma_1, \ldots, \sigma_n)$ with the Hankel singular values $\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_n > 0$. The Hankel singular values are the positive square roots of the eigenvalues of the product of the Gramians PQ, $\sigma_k = \sqrt{\lambda_k(PQ)}$. They are system invariants, i.e., they are independent of the chosen realization of (1) as they are preserved under state-space transformations.

Given the LTI system (1) in a non-balanced coordinate form and the Gramians P and Q satisfying (9), the transformation matrix T which yields an LTI system in balanced coordinates can be computed via the so-called square root algorithm as follows:

- Compute the Cholesky factors S and R of the Gramians such that $P = S^T S$, $Q = R^T R$.
- Compute the singular value decomposition of $SR^T = \Phi \Sigma \Gamma^T$, where Φ and Γ are orthogonal matrices and Σ is a diagonal matrix with the Hankel singular values on its diagonal. $T = S^T \Phi \Sigma^{-\frac{1}{2}}$ yields the balancing transformation (note that $T^{-1} = \Sigma^{\frac{1}{2}} \Phi^T S^{-T} = \Sigma^{-\frac{1}{2}} \Gamma^T R$).
- Partition Φ, Σ, Γ into blocks of corresponding sizes,

$$\Sigma = \begin{bmatrix} \Sigma_1 & \\ & \Sigma_2 \end{bmatrix}, \Phi = \begin{bmatrix} \Phi_1 \\ \Phi_2 \end{bmatrix}, \Gamma^T = \begin{bmatrix} \Gamma_1^T \\ \Gamma_2^T \end{bmatrix},$$

with $\Sigma_1 = \mathrm{diag}(\sigma_1, \ldots, \sigma_r)$ and apply T to (1) to obtain (7) with

$$T^{-1}AT = \begin{bmatrix} W^T A V & A_{12} \\ A_{21} & A_{22} \end{bmatrix}, \ T^{-1}B = \begin{bmatrix} W^T B \\ B_2 \end{bmatrix}, \tag{10}$$

and $CT = [CV \ C_2]$ for $W = R^T \Gamma_1 \Sigma_1^{-\frac{1}{2}}$ and $V = S^T \Phi_1 \Sigma_1^{-\frac{1}{2}}$. Preserving the r dominant Hankel singular values by truncating the rest yields the reduced-order model as in (5).

As $W^T V = I$, balanced truncation is an oblique projection method. The reduced-order model is stable with the Hankel singular values $\sigma_1, \ldots, \sigma_r$. It can be shown that if $\sigma_r > \sigma_{r+1}$, the error bound

$$\|G(\cdot) - \widetilde{G}(\cdot)\|_{\mathcal{H}_\infty} \leq 2 \sum_{k=r+1}^{n} \sigma_k \tag{11}$$

holds. Given an error tolerance, this allows to choose the appropriate order r of the reduced system in the course of the computations.

As the explicit computation of the balancing transformation T is numerically hazardous, one usually uses the equivalent balancing-free square root algorithm (Varga 1991) in which orthogonal bases for the column spaces of V and W are computed. The so obtained ROM is no longer balanced, but preserves all other properties (error bound, stability). Furthermore, it is shown in Benner et al. (2000) how to implement the balancing-free square root algorithm using low-rank approximations to S and R without ever

M

having to resort to the square solution matrices P and Q of the Lyapunov equations (9). This yields an efficient algorithm for balanced truncation for LTI systems with large dense matrices. For systems with large-scale sparse A efficient algorithms based on sparse solvers for (9) exist; see Benner (2006).

By replacing the solution matrices P and Q of (9) by other pairs of positive (semi-)definite matrices characterizing alternative controllability and observability related system information, one obtains a family of model reduction methods including stochastic/bounded-real/positive-real balanced truncation. These can be used if further properties like minimum phase, passivity, etc. are to be preserved in the reduced-order model; for further details, see Antoulas (2005) and Obinata and Anderson (2001).

The balanced truncation yields good approximation at high frequencies as $\widetilde{G}(\iota\omega) \to G(\iota\omega)$ for $\omega \to \infty$ (as $\widetilde{D} = D$), while the maximum error is often attained for $\omega = 0$. For a perfect match at zero and a good approximation for low frequencies, one may employ the *singular perturbation approximation* (SPA, also called balanced residualization). In view of (7) and (10), balanced truncation can be seen as partitioning $T^{-1}x$ according to (10) into $[x_1^T, x_2^T]^T$ and setting $x_2 \equiv 0$ (i.e., $\dot{x}_2 = 0$ as well). For SPA, one only sets $\dot{x}_2 = 0$, such that

$$\dot{x}_1 = WTAVx_1 + A_{12}x_2 + WTBu,$$

$$0 = A_{21}x_1 + A_{22}x_2 + B_2u.$$

Solving the second equation for x_2 and inserting it into the first equation yields

$$\dot{x}_1 = \left(WTAV - A_{12}A_{22}^{-1}A_{21}\right)x_1$$
$$+ \left(WTB - A_{12}A_{22}^{-1}B_2\right)u.$$

For the output equation, it follows

$$\tilde{y} = \left(CV - C_2A_{22}^{-1}A_{21}\right)x_1 + \left(D - C_2A_{22}^{-1}B_2\right)u.$$

This reduced-order model makes use of the information in the matrices A_{12}, A_{21}, A_{22}, B_2, and C_2 discarded by balanced truncation. It fulfills

$\widetilde{G}(0) = G(0)$ and the error bound (11); moreover, it preserves stability.

Besides SPA, another related truncation method that is not based on projection is *optimal Hankel norm approximation* (HNA). The description of HNA is technically quite involved; for details, see Zhou et al. (1996) and Glover (1984). It should be noted that the so obtained ROM usually has similar stability and accuracy properties as for balanced truncation.

Interpolation-Based Methods

Another family of methods for MOR is based on (rational) interpolation. The unifying feature of the methods in this family is that the original TFM (2) is approximated by a rational matrix function of lower degree satisfying some interpolation conditions (i.e., the original and the reduced-order TFM coincide, e.g., $G(s_0) = \widetilde{G}(s_0)$ at some predefined value s_0 for which $A - s_0E$ is nonsingular). Computationally this is usually realized by certain Krylov subspace methods.

The classical approach is known under the name of *moment-matching* or *Padé(-type) approximation*. In these methods, the transfer functions of the original and the reduced order systems are expanded into power series, and the reduced-order system is then determined so that the first coefficients in the series expansions match. In this context, the coefficients of the power series are called moments, which explains the term moment matching.

Classically the expansion of the TFM (2) in a power series about an expansion point s_0

$$G(s) = \sum_{j=0}^{\infty} M_j(s_0)(s - s_0)^j \qquad (12)$$

is used. The moments $M_j(s_0)$, $j = 0, 1, 2, \ldots$, are given by

$$M_j(s_0) = -C\left[(A - s_0E)^{-1}E\right]^j(A - s_0E)^{-1}B.$$

Consider the (block) Krylov subspace $\mathcal{K}_k(F, H) = \text{span}\{H, FH, F^2H, \ldots, F^{k-1}H\}$ for $F = (A - s_0E)^{-1}E$ and $H = -(A - s_0E)^{-1}B$ with

an appropriately chosen expansion point s_0 which may be real or complex. From the definitions of A, B, and E, it follows that $F \in \mathbb{K}^{n \times n}$ and $H \in \mathbb{K}^{n \times m}$, where $\mathbb{K} = \mathbb{R}$ or $\mathbb{K} = \mathbb{C}$ depending on whether s_0 is chosen in $\mathbb{R}$ or in $\mathbb{C}$. Considering $\mathcal{K}_k(F, H)$ column by column, this leads to the observation that the number of column vectors in $\{H, FH, F^2 H, \ldots, F^{k-1} H\}$ is given by $r = m \cdot k$, as there are k blocks $F^j H \in \mathbb{K}^{n \times m}$, $j = 0, \ldots, k - 1$. In the case when all r column vectors are linearly independent, the dimension of the Krylov subspace $\mathcal{K}_k(F, H)$ is $m \cdot k$. Assume that a unitary basis for this block Krylov subspace is generated such that the column space of the resulting unitary matrix $V \in \mathbb{C}^{n \times r}$ spans $\mathcal{K}_k(F, G)$. Applying the Galerkin projection $\Pi = V V^*$ to (1) yields a reduced system whose TFM satisfies the following (Hermite) interpolation conditions at s_0:

$$\widetilde{G}^{(j)}(s_0) = G^{(j)}(s_0), \quad j = 0, 1, \ldots, k - 1.$$

That is, the first $k - 1$ derivatives of G and $\widetilde{G}$ coincide at s_0. Considering the power series expansion (12) of the original and the reduced-order TFM, this is equivalent to saying that at least the first k moments $\widetilde{M}_j(s_0)$ of the transfer function $\widetilde{G}(s)$ of the reduced system (3) are equal to the first k moments $M_j(s_0)$ of the TFM $G(s)$ of the original system (1) at the expansion point s_0:

$$M_j(s_0) = \widetilde{M}_j(s_0), \quad j = 0, 1, \ldots, k - 1.$$

If further the r columns of the unitary matrix W span the block Krylov subspace $\mathcal{K}_k(F, H)$ for $F = (A - s_0 E)^{-T} E$ and $H = -(A - s_0 E)^{-T} C^T$, applying the Petrov-Galerkin projection $\Pi = V(W^* V)^{-1} W^*$ to (1) yields a reduced system whose TFM matches at least the first $2k$ moments of the TFM of the original system.

Theoretically, the matrix V (and W) can be computed by explicitly forming the columns which span the corresponding Krylov subspace $\mathcal{K}_k(F, H)$ and using the Gram-Schmidt algorithm to generate unitary basis vectors for $\mathcal{K}_k(F, H)$. The forming of the moments (the Krylov subspace blocks $F^j H$) is numerically precarious and has to be avoided under all

circumstances. Using Krylov subspace methods to achieve an interpolation-based ROM as described above is recommended. The unitary basis of a (block) Krylov subspace can be computed by employing a (block) Arnoldi or (block) Lanczos method; see, e.g., Antoulas (2005), Golub and Van Loan (2013), and Freund (2003).

In the case when an oblique projection is to be used, it is not necessary to compute two unitary bases as above. An alternative is then to use the nonsymmetric Lanczos process (Golub and Van Loan 2013). It computes bi-unitary (i.e., $W^* V = I_r$) bases for the above mentioned Krylov subspaces and the reduced-order model as a by-product of the Lanczos process. An overview of the computational techniques for moment-matching and Padé approximation summarizing the work of a decade is given in Freund (2003) and the references therein.

In general, the discussed MOR approaches are instances of rational interpolation. When the expansion point is chosen to be $s_0 = \infty$, the moments are called Markov parameters and the approximation problem is known as partial realization. If $s_0 = 0$, the approximation problem is known as Padé approximation.

As the use of one single expansion point s_0 leads to good approximation only close to s_0, it might be desirable to use more than one expansion point. This leads to multipoint moment-matching methods, also called rational Krylov methods; see, e.g., Ruhe and Skoogh (1998), Antoulas (2005), and Freund (2003).

In contrast to balanced truncation, these (rational) interpolation methods do not necessarily preserve stability. Remedies have been suggested; see, e.g., Freund (2003).

The use of complex-valued expansion points will lead to a complex-valued reduced-order system (3). In some applications (in particular, in case the original system is real valued), this is undesired. In that case one can always use complex-conjugate pairs of expansion points as then the entire computations can be done in real arithmetic.

The methods just described provide good approximation quality locally around the expansion

points. They do not aim at a global approximation as measured by the $\mathcal{H}_2$- or $\mathcal{H}_\infty$-norms. In Gugercin et al. (2008), an iterative procedure is presented which determines locally optimal expansion points w.r.t. the $\mathcal{H}_2$-norm approximation under the assumption that the order r of the reduced model is prescribed and only 0th- and 1st-order derivatives are matched. Also, for multi-input multi-output systems (i.e., m and p in (1) are both larger than one), no full moment matching is achieved, but only tangential interpolation: $G(s_j)b_j = \widetilde{G}(s_j)b_j$, $c_j^* G(s_j) = c_j^* \widetilde{G}(s_j)$, $c_j^* G'(s_j)b_j = c_j^* \widetilde{G}'(s_j)b_j$, for certain vectors b_j, c_j determined together with the optimal s_j by the iterative procedure.

Tools

Almost all commercial software packages for structural dynamics include modal analysis/truncation as a means to compute a ROM. Modal truncation and balanced truncation are available in the MATLAB® Control System Toolbox and the MATLAB® Robust Control Toolbox.

Numerically reliable, well-tested, and efficient implementations of many variants of balancing-based MOR methods as well as Hankel norm approximation and singular perturbation approximation can be found in the Subroutine Library In Control Theory (SLICOT, http://www.slicot.org) (Varga 2001). Easy-to-use MATLAB interfaces to the Fortran 77 subroutines from SLICOT are available in the SLICOT Model and Controller Reduction Toolbox (http://slicot.org/matlab-toolboxes/basic-control); see Benner et al. (2010). An implementation of moment matching via the (block) Arnoldi method is available in MOR for ANSYS®(http://modelreduction.com/Software.html).

There exist benchmark collections with mainly a number of LTI systems from various applications. There one can find systems in computer-readable format which can easily be used to test new algorithms and software:

- Oberwolfach Model Reduction Benchmark Collection
  http://simulation.uni-freiburg.de/downloads/benchmark/
- NICONET Benchmark Examples
  http://www.icm.tu-bs.de/NICONET/benchmodred.html

The MOR WiKi http://morwiki.mpi-magdeburg.mpg.de/morwiki/ is a platform for MOR research and provides discussions of a number of methods, links to further software packages (e.g., MOREMBS and MORPACK), as well as additional benchmark examples.

Summary and Future Directions

MOR of LTI systems can now be considered as an established computational technique. Some open issues still remain and are currently investigated. These include methods yielding good approximation in finite frequency or time intervals. Though numerous approaches for these tasks exist, methods with sharp local error bounds are still desirable. A related problem is the reduction of closed-loop systems and controller reduction. Also, the generalization of the methods discussed in this essay to descriptor systems (i.e., systems with DAE dynamics), second-order systems, or unstable LTI systems has only been partially achieved. An important problem class getting a lot of current attention consists of (uncertain) parametric systems. Here it is important to preserve parameters as symbolic quantities in the ROM. Most of the current approaches are based in one way or another on interpolation. MOR for nonlinear systems has also been a research topic for decades. Still, the development of satisfactory methods in the context of control design having computable error bounds and preserving interesting system properties remains a challenging task.

Abstract

The fundamentals and design principles of model reference adaptive control (MRAC) are described. The controller structure and adaptive algorithms are delineated. Stability and convergence properties are summarized.

Keywords

Certainty equivalence; Lyapunov-SPR design; MIT rule

Introduction

Model reference adaptive control (MRAC) is an important adaptive control approach, supported by rigorous mathematical analysis and effective design toolsets. It is made up of a feedback control law that contains a controller $C(s, \theta_c)$ and an adjustment mechanism that generates the controller parameter updates $\theta_c(t)$ online. While different MRAC configurations can be found in the literature, the structure shown in Fig. 1 is commonly used and includes all the basic components of an MRAC system. The prominent features of MRAC are that it incorporates a reference model which represents the desired

M
Model Reference Adaptive Control, Fig. 1 Schematic of MRAC

input–output behavior and that the controller and adaptation law are designed to force the response of the plant, y_p, to track that of the reference model, y_m, for any given reference input r.

Different approaches have been used to design MRAC, and each may lead to a different implementation scheme. The implementation schemes fall into two categories: direct and indirect MRAC. The former updates the controller parameters θ_c directly using an adaptive law, while the latter updates the plant parameters θ_p first using an estimation algorithm and then updates θ_c by solving, at each time t, certain algebraic equations that relate θ_c with the online estimates of θ_p. In both direct and indirect MRAC schemes, the controller structure is kept the same as that which would be used in the case that the plant parameters are known.

MRC Controller Structure

Consider the design objective of model reference control (MRC) for linear time-invariant systems: Given a reference model $M(s)$, find a control law such that the closed-loop system is stable and $y_p \to y_m$ as $t \to \infty$ for any bounded reference signal r.

For the case of known plant parameters, the MRC objective can be achieved by designing the controller so that the closed-loop system has a transfer function equal to $M(s)$. This

is the so-called model matching condition. To assure the existence of a causal controller that meets the model matching condition and guarantees internal stability of the closed-loop system, the following assumptions are essential:

- A1. The plant has a stable inverse, and the reference model is chosen to be stable.
- A2. The relative degree of $M(s)$ is equal to or greater than that of the plant $G_p(s)$. Herein, the relative degree of a transfer function refers to the difference between the orders of the denominator and numerator polynomials.

It should be noted that these assumptions are imposed to the MRC problem so that there is enough structural flexibility in the plant and in the reference model to meet the control objectives. A1 is necessary for maintaining internal stability of the system while meeting the model matching condition, and A2 is needed to ensure the causality of the controller. Both assumptions are essential for non-adaptive applications when the plant parameters are known, let alone for the adaptive cases when the plant parameters are unknown.

The reference model plays an important role in MRAC, as it will define the feasibility of MRAC design as well as the performance of the resulting closed-loop MRAC system. The reference model should reflect the desired closed-loop performance. Namely, any time-domain or frequency-domain specifications, such as time constant, damping ratio, natural frequency, bandwidth, etc., should be properly reflected in the chosen transfer function $M(s)$.

The controller structure for the MRAC is derived with these assumptions for the known plant case and extended to the adaptive case by combining it with a proper adaptive law. Under assumptions A1–A2, there exist infinitely many control solutions C that will achieve the MRC design objective for a given plant transfer function $G_p(s)$. Nonetheless, only those extendable to MRAC with the simplest structure are of interest. It is known that if a special controller structure with the following parametrization is imposed, then the solution to the model matching

condition, in terms of the ideal parameter θ_c^*, will be unique:

$$u_p = \theta_1^{*T}\omega_1 + \theta_2^{*T}\omega_2 + \theta_3^{*T}y_p + c_0^* r = \theta_c^{*T}\omega$$

where $\theta_c^* \in R^{2n}$, n is the order of the plant,

$$\theta_c^* = \begin{bmatrix} \theta_1^* \\ \theta_2^* \\ \theta_3^* \\ c_0^* \end{bmatrix}, \omega = \begin{bmatrix} \omega_1 \\ \omega_2 \\ y_p \\ r \end{bmatrix}$$

and $\omega_1, \omega_2 \in R^{n-1}$ are signals internal to the controller generated by stable filters (Ioannou and Sun 1996).

This MRC control structure is particularly appealing for adaptive control development, as the parameters appear linearly in the control law expression, leading to a convenient linear parametric model for adaptive algorithm development.

Adaptation Algorithm

Design of adaptive algorithms for parameter updating can be pursued in several different approaches, thereby resulting in different MRAC schemes. Three direct design approaches, namely, the Lyapunov-SPR, the certainty equivalence, and the MIT rule, will be briefly described together with indirect MRAC.

Lyapunov-SPR Design

One popular MRAC algorithm is derived using Lyapunov's direct method and the Meyer-Kalman-Yakubovich (MKY) Lemma based on the strictly positive real (SPR) argument. The concept of SPR transfer functions originates from network theory and is related to the driving point impendence of dissipative networks. The MKY Lemma states that given a stable transfer function $M(s)$ and its realization (A, B, C, d) where $d \geq 0$ and all eigenvalues of the matrix A are in the open left half plane: If $M(s)$ is SPR, then for any given positive definite matrix $L = L^T > 0$, there exists a scalar $\nu > 0$, a vector q, and a $P = P^T > 0$ such that

$$A^T P + PA = -qq^T - \nu L$$
$$PB - C = \pm q\sqrt{2d}$$

By choosing $M(s)$ to be SPR, one can formulate a Lyapunov function consisting of the state tracking and parameter estimation errors and use the MKY Lemma to define the adaptive law that will force the derivative of the Lyapunov function to be semi-negative definite. The resulting adaptive law has the following simple form:

$$\dot{\theta} = -\Gamma e_1 \omega \text{sign}(c_0^*)$$

where $e_1 = y_p - y_m$ is simply the tracking error and $c_0^* = k_m/k_p$ with k_m, k_p being the high frequency gain of the transfer function for the reference model $M(s)$ and the plant $G_p(s)$, respectively. This algorithm, however, applies only to systems with relative degree equal to 0 or 1, which is implied by the SPR condition imposed on $M(s)$ and assumption A2.

The Lyapunov-SPR-based MRAC design is mathematically elegant in its stability analysis but is restricted to a special class of systems. While it can be extended to more general cases with relative degrees equal to 2 and 3, the resulting control law and adaptive algorithm become much more complicated and cumbersome as efforts must be made to augment the control signal in such a way that the MKY Lemma is applicable to the "reformulated" reference model.

Certainty Equivalence Design

For more general cases with a high relative degree, another design approach based on "certainty equivalence" (CE) principle is preferred, due to the simplicity in its design as well as its robustness properties in the presence of modeling errors. This approach treats the design of the adaptive law as a parameter estimation problem, with the estimated parameters being the controller parameter vector θ_c^*. Using the specific linear formulation of the control law and assuming that θ_c^* satisfies the model matching condition, one can show that the ideal controller parameter satisfies the following parametric equation:

$$z = \theta_c^{*T} \omega_p$$

with

$$z = M(s)u_p, \omega_p = \begin{bmatrix} M(s)\omega_1 \\ M(s)\omega_2 \\ M(s)y_p \\ y_p \end{bmatrix}$$

This parametric model allows one to derive adaptive laws to estimate the unknown controller parameter θ_c^* using standard parameter identification techniques, such as the gradient and least squares algorithms. The corresponding MRAC is then implemented in the CE sense where the unknown parameters are replaced by their estimated value. It should be noted that a CE design does not guarantee closed-loop stability of the resulting adaptive system, and additional analysis has been carried out to establish closed-loop stability.

MIT Rule

Besides the Lyapunov-SPR and CE approaches mentioned earlier, the direct MRAC problem can also be approached using the so-called MIT rule, an early form of MRAC developed in the 1950s–1960s in the Instrumentation Laboratory at MIT for flight control. The designer defines a cost function, e.g., a quadratic function of tracking error, and then adjusts parameters in the direction of steepest descent. The negative gradient of the cost function is usually calculated through the sensitivity derivative approach. The formulation is quite flexible, as different forms of MIT rule can be derived by changing the cost function following the same procedure and reusing the same sensitivity functions. Despite its effectiveness in some practical applications, MRAC systems designed with MIT rule have had stability and robustness issues.

Indirect MRAC

While most of the MRAC systems are designed as direct adaptive systems, indirect MRAC systems can also be developed which explicitly estimate the plant parameter θ_p as an intermediate step. The adaptive law for an indirect MRAC includes two basic components: one for estimating the plant parameters and another for calculating the controller parameters based on the estimated plant parameters. This approach would be preferred if the plant transfer function is partially known, in which case the identification of the remaining unknown parameters represents a less complex problem. For example, if the plant has no zeros, the indirect scheme estimates $n + 1$ parameters, while the direct scheme has to estimate $2n$ parameters.

Indirect MRAC is a CE-based design. As such, the design is intuitive but the design process does not guarantee closed-loop stability, and separate analysis has to be carried out to establish stability. Except for systems with a low number of zeros, the "feasibility" problem could also complicate the matter, in the sense that the MRC problem may not have a solution for the estimated plant at some time instants even though the solution exists for the real plant. This problem is unique to the indirect design, and several mitigating solutions have been found at the expense of more complicated adaptation or control algorithms.

Stability, Robustness, and Parameter Convergence

Stability for MRAC often refers to the properties that all signals are bounded and tracking error converges to zero asymptotically. Robustness for adaptive systems implies that signal boundedness and tracking error convergence (to a small residue set) will be preserved in the presence of small perturbations such as disturbances, un-modeled dynamics, and time-varying parameters. For different MRAC schemes, different approaches are used to establish their properties.

For the Lyapunov-SPR-based MRAC systems, stability is established in the design process where the adaptive law is derived to enforce a Lyapunov stability condition. For CE-based designs, establishing stability for the closed-loop MRAC system is a nontrivial exercise for both direct and indirect schemes. Using properly normalized adaptive laws for parameter

estimation, however, stability can be proved for direct and indirect MRAC schemes. For MRAC systems designed with the MIT rule, local stability can be established under more restrictive conditions, such as when the parameters are close to the ideal ones.

It should be noted that the adaptive control algorithm in the original form has been shown to have robustness issues, and extensive publications in the 1980s and 1990s were devoted to robust adaptive control in attempts to mitigate the problem. Many modifications have been proposed and shown to be effective in "robustifying" the MRAC; interested readers are referred to the article on ▶ Robust Adaptive Control for more details.

Parameter convergence is not an intrinsic requirement for MRAC, as tracking error convergence can be achieved without parameter convergence. It has been shown, however, that parameter convergence could enhance robustness, particularly for indirect schemes. As in the case for parameter identification, a persistent excitation (PE) condition needs to be imposed on the regression signal to assure parameter convergence in MRAC. In general, PE is accomplished by properly choosing the reference input r. It can be established for most MRAC approaches that parameter convergence is achieved if, in addition to conditions required for stability, the reference input r is sufficiently rich of order $2n$, $\dot{r}$ is bounded, and there is no pole-zero cancelation in the plant transfer function. A signal is called to be sufficiently rich of order m if it contains at least $m/2$ distinct frequencies.

Summary and Future Directions

MRAC incorporates a reference model to capture the desired closed-loop responses and designs the control law and adaptation algorithm to force the output of the plant to follow the output of the reference model. Several different design approaches are available. Stability, robustness, and parameter convergence have been established for different MRAC designs with appropriate assumptions.

MRAC had been a very active and fruitful research topic from the 1960s to 1990s, and it formed important foundations for modern adaptive control theory. It also found many successful applications ranging from chemical process controls to automobile engine controls. More recent efforts have been mostly devoted to integrating it with other design approaches to treat nonstandard MRAC problems for nonlinear and complex dynamic systems.

Recommended Reading

MRAC has been well covered in several textbooks and research monographs. Astrom and Wittenmark (1994) presented different MRAC schemes in a tutorial fashion. Narendra and Annaswamy (1989) focused on stability of deterministic MRAC systems. Ioannou and Sun (1996) covered the detailed derivation and analysis of different MRAC schemes and provided a unified treatment for their stability and robustness analysis. MRAC systems for discrete-time (Goodwin and Sin 1984) and for nonlinear (Krstic et al. 1995) processes are also well explored.

Model-Based Performance Optimizing Control

Sebastian Engell
Fakultät Bio- und Chemieingenieurwesen,
Technische Universität Dortmund, Dortmund,
Germany

Abstract

In many applications, e.g., in chemical process control, the purpose of control is to achieve an optimal performance of the controlled system despite the presence of significant uncertainties about its behavior and of external disturbances. Tracking of set points is often required for lower-level control loops, but at the system level in most cases, this is not the primary concern and may even be counterproductive. In this entry, the use of dynamic online optimization on a moving finite horizon to realize optimal system performance is discussed. By real-time optimization, a performance-oriented or economic cost criterion is minimized or maximized over a finite horizon while the usual control specifications enter as constraints but not as set points. This approach integrates the computation of optimal set-point trajectories and of the regulation to these trajectories.

Keywords

Model-predictive control (MPC); Integrated optimization and control; Real-time optimization (RTO); Performance optimizing control; Process control

Introduction

From a systems point of view, the purpose of automatic feedback control (and that of manual control as well) in many cases is *not* primarily to keep the controlled variables at their set points as well as possible or to track dynamic set-point changes but to operate the system such that its *performance* is optimized in the presence of disturbances und uncertainties, exploiting the information gained in real time from the available measurements. This holds generally for the higher control layers in the process industries but similarly for many other applications. Suppose that, for example, the availability of cooling water at a lower temperature than assumed as a worst case during plant design enables plant operation at a higher throughput. In this case, what sense does it make to enforce the nominal operating point by tight feedback control? For a combustion engine, the goal is to achieve the desired torque with minimum consumption of fuel. For a cooling system, the goal is to keep the temperature of the goods or of a room within certain bounds with minimum consumption of energy, possibly weighted against the wear of the equipment. To regulate some variables to their set points may help to achieve these goals but it is not the real performance target for the overall system. Feedback control loops therefore usually are part of control hierarchies that establish good performance of the overall system and the meeting of constraints on its operation.

There are four main approaches to the integration of feedback control with system performance optimization:

- Choice of regulated variables such that, implicitly via the regulation of these variables to their set points, the performance of the overall system is close to optimal (see the chapter on ▸ Control Structure Selection).
- Tracking of necessary conditions of optimality where variables which determine the optimal operating policy are kept at or close to their constraints. This is a widespread approach especially in chemical batch processes where, e.g., the feeding of reactants is such that the maximum cooling power available is used (Finkler et al. 2014); see also the chapter on ▸ Control and Optimization of Batch Processes).

In these two approaches, the choice of the optimal set points or constraints to be tracked is done off-line, and they are then implemented by the feedback layer of the process control hierarchy (see the chapter on ▸ Control Hierarchy of Large Processing Plants: An Overview).

- Combination of a regulatory (tracking) feedback control with an optimization of the set points or system trajectories (called real-time optimization in the process industries) (see the chapter on ▶ Real-Time Optimization of Industrial Processes).
- Reformulation of model-predictive control such that the control target is not the tracking of references but the optimization of the system performance over a finite horizon, taking constraints of system variables or inputs into account directly within the online optimization. Here, the optimization is performed with a dynamic model, in contrast to the steady-state optimization in real-time optimization or in the choice of self-optimizing control structures.

The first three approaches are currently state of the art in the process industries. Tracking of necessary conditions of optimality is usually designed based on process insight rather than based upon a rigorous analysis, and the same holds for the selection of regulatory control structures. The last one is the most challenging approach in terms of the required models and algorithms and computing power, and its theoretical foundations are still under development. But on the other hand, it also has the highest potential in terms of the resulting performance of the controlled system, and it is structurally simple and easier to tune because the natural performance specification does not have to be translated into controller tunings, weights, etc. Therefore, the idea of direct model-based performance optimizing control has found much attention in process control in recent years.

The four approaches above are discussed in more detail below. We also provide some historical notes and outline some areas of continuing research.

Performance Optimization by Regulation to Fixed Set Points

Morari et al. (1980) stated that the objective in the synthesis of a control structure is "to translate the economic objectives into process control objectives." A subgoal in this "translation" is to select the regulatory control structure of a process such that steady-state optimality of process operations is realized to the maximum extent possible by driving the selected controlled variables to suitably chosen set points. A control structure with this property was termed "self-optimizing control" by Skogestad (2000). It should adjust the manipulated variables by keeping a function of the measured variables constant such that the process is operated at the economically optimal steady state in the presence of disturbances. From a system point of view, a control structure that yields nice transient responses and tight control of the selected variables may be of little use or even counterproductive if keeping the regulated variables at their set points does not improve the performance of the system. Ideally, in the steady state, a similar performance is obtained as it would be realized by optimizing the stationary values of the operational degrees of freedom of the system for known disturbances d and a perfect model. By regulating the controlled variables to their set points at the steady state in the presence of disturbances, a mapping $u = f(y_{set}, d)$ is implicitly realized which should be an approximation of the performance optimizing inputs $u_{opt}(d)$. The choice of the self-optimizing control structure takes only the steady-state performance into account, not the dynamic reaction of the controlled plant. An extension of the approach to include also the dynamic behavior can be found in Pham and Engell (2011).

Tracking of Necessary Conditions of Optimality

Very often, the optimal operation of a system in a certain phase of its evolution or under certain conditions is defined by some variables being at their constraints. If these variables are known and the conditions can be monitored, a switching control structure can be built that keeps the (possibly changing) set of critical variables at their constraints despite inaccuracies of the model, external disturbances, etc. In fact it turns out that such control schemes can, in the case of varying

parameters and in the presence of disturbances, perform as good as sophisticated model-based optimization schemes (Finkler et al. 2013).

Performance Optimization by Steady-State Optimization and Regulation

A well-established approach to create a link between regulatory control and the optimization of the performance of a system is to compute the set points of the controllers by an optimization layer. In process operations, this layer is called real-time optimization (RTO) (see, e.g., Marlin and Hrymak (1997) and the references therein). An RTO system is a model-based, upper-level control system that is operated in closed loop and provides set points to the lower-level control systems in order to maintain the process operation as close as possible to the economic optimum. It usually comprises an estimation of the plant state and plant parameters from the measured data and an economic or otherwise performance-related optimization of the operating point using a detailed nonlinear steady-state model.

As the RTO system employs a stationary process model and the optimization is only performed if the plant is approximately in a steady state, the time between successive RTO steps must be large enough for the plant to reach a new steady state after the last commanded move. This structure is based upon a separation of concerns and of time-scales between the RTO system and the process control system. The RTO system optimizes the system economics on a medium timescale (shifts to days), while the control system provides tracking and disturbance rejection on shorter timescales from seconds to hours.

As an approximation to real-time optimization with a nonlinear rigorous plant model, in many MPC implementations nowadays, an optimization of the steady-state values based on the linear model that is used in the MPC controller is implemented. Then the gain matrix of the model must be estimated carefully to obtain good results.

Performance Optimizing Control

Model-predictive control has become the standard solution for demanding control problems in the process industries (Qin and Badgwell 2003) and increasingly is used also in other domains. The core idea is to employ a model to predict the effect of the future manipulated variables on the future controlled variables over a finite horizon and to use optimization to determine sequences of inputs which minimize a cost function over the so-called prediction horizon. In the unconstrained case with linear plant model and a quadratic cost function, the optimal control moves can be computed by a closed-form solution. When constraints on inputs, outputs, and possibly also state variables are present, for a quadratic cost function and linear plant model, the optimization problem becomes a quadratic program (QP) that has to be solved in real time.

When the system dynamics are nonlinear and linear models are only sufficiently accurate within narrow operation bands, as is the case in many chemical processes, nonlinear model predictive control which is based on nonlinear models of the process dynamics provides superior performance and therefore has met increasing interest both in theory and in practice. The classical formulation of nonlinear model-predictive tracking control (TC) is

$$\min_{u} \phi_{TC} \left(\bar{y}, u \right)$$

$$\phi_{TC} = \sum_{n=1}^{N} \left(\sum_{i=1}^{P} \gamma_{n,i} \left(y_{n,ref} \left(k - i \right) - \bar{y}_n \left(k + i \right) \right)^2 \right) + \sum_{l=1}^{R} \left(\sum_{j=1}^{M} \alpha_{l,j} \Delta u_l^2 (k + j) \right)$$

s.t.

$$x(i+1) = f(x(i), z(i), u(i), i), i = k, \ldots, k+P$$

$$0 = g(x(i), z(i), u(i), i), i = k, \ldots, k+P$$

$$y(i+1) = h(x(i+1), u(i)), i = k, \ldots, k+P$$

$$x_{min} \le x(i) \le x_{max}, i = k, \ldots, k+P$$

$$y_{min} \le \bar{y}(i) \le y_{max}, i = k, \ldots, k+P$$

$$u_{min} \le u(i) \le u_{max}, i = k, \ldots, k+M$$

$$-\Delta u_{min} \le \Delta u(i) \le \Delta u_{max}, i = k, \ldots, k+M$$

$$u(i) = u(i-1) + \Delta u(i), i = k, \ldots, k+M$$

$$u(i) = u(k+M), \forall i > k+M.$$

Here f and g represent the plant model in the form of a system of differential-algebraic Equations and h is the output function. P is the length of the prediction horizon and M is the length of the control horizon, and $y_1, \cdots, y_N$ are the predicted control outputs, $u_1, \cdots, u_R$ are the control inputs. α and γ represent the weights on the control inputs and the control outputs, respectively. y_{ref} refers to the set point or the desired output trajectory, and $\hat{y}(i)$ are the corrected model predictions. N is number of the controlled outputs, and R is the number of the control inputs. Compensation for plant-model mismatch and unmeasured disturbances is usually done using the bias correction equations:

$$d(k) = y^{meas}(k) - y(k),$$

$$\bar{y}(k+i) = y(k+i) + d(k), i = k, \ldots, k+P.$$

The idea of direct performance optimizing control (POC) is to replace this formulation by a performance-related objective function:

$$\min_u \phi_{POC}(y, u)$$
$$\phi_{POC} = \sum_{l=1}^{R} \left(\sum_{j=1}^{M} \alpha_{l,j} \Delta u_l^2(k+j) \right) - \left(\sum_{i=1}^{P} \beta_i \psi(k+i) \right).$$

Here $\psi(k+i)$ represents the value of the performance cost criterion at the time step $[k+i]$.

The optimization of the future control moves is subject to the same constraints as before. In addition, instead of reference tracking, constraints are formulated for all outputs that are critical for the operation of the system or its performance, e.g., product quality specifications or limitations of the equipment. In contrast to reference tracking, these constraints usually are one-sided (inequalities) or define operation bands. By this formulation, e.g., the production revenues can be maximized online over a finite horizon, considering constraints on product purities and waste stream impurities. Feedback enters into the computation by the initialization of the model with a new initial state that is estimated from the available measurements of system variables and by the bias correction. Thus, direct performance optimizing control realizes an online optimization of all operational degrees of freedom in a feedback structure without tracking of a priori fixed set points or reference trajectories. The regularization term that penalizes control moves is added to the purely economic objective function to obtain smoother solutions.

This approach has several advantages over a combined steady-state optimization/ linear MPC scheme:

- Immediate reaction to disturbances, no waiting for the plant to reach a steady state is required.
- "Overregulation" is avoided – no variables are forced to fixed set points and all degrees of freedom can be used to improve the (economic) performance of the plant.
- Performance goals and process constraints do not have to be mapped to a control cost that defines a compromise between different goals. In this way, the formulation of the optimization problem and the tuning are facilitated compared to achieving good performance by tuning of the weights of a tracking formulation.
- More constraints than available manipulated variables can be handled as well as more manipulated variables than variables that have to be regulated.
- No inconsistency arises from the use of different models on different layers.
- The overall scheme is structurally simple.

M

Similar to any NMPC controller that is designed for reference tracking, a successful implementation will require careful engineering such that as many uncertainties as possible are compensated by simple feedback controllers and only the key dynamic variables are handled by the optimizing controller based on a rigorous model of the essential dynamics and of the stationary relations of the plant without too much detail.

History and Examples

The idea of economic or performance optimizing control originated from the process control community. The first papers on directly integrating economic considerations into model-predictive control Zanin et al. (2000) proposed to achieve a better economic performance by adding an economic term to a classical tracking performance criterion and applied this to the control of a fluidized bed catalytic cracker. Helbig et al. (2000) discussed different ways to integrate optimization and feedback control including direct dynamic optimization for the example of a semi-batch reactor. Toumi and Engell (2004) and Erdem et al. (2004) demonstrated online performance optimizing control schemes for simulated moving bed (SMB) chromatographic separations in lab scale. SMB processes are periodic processes and constitute prototypical examples where additional degrees of freedom can be used to simultaneously optimize *system* performance and to meet product specifications. Bartusiak (2005) reported already industrial applications of carefully engineered performance optimizing NMPC controllers.

Direct performance optimizing control was suggested as a promising general new control paradigm for the process industries by Rolandi and Romagnoli (2005), Engell (2006, 2007), Rawlings and Amrit (2009), and others. Meanwhile it has been demonstrated in many simulation studies that direct optimization of a performance criterion can lead to superior economic performance compared to classical tracking (N)MPC, e.g., Ochoa et al. (2010) for a

bioethanol process and Idris and Engell (2012) for a reactive distillation column.

Further Issues

Modeling and Robustness

In a direct performance optimizing control approach, sufficiently accurate dynamic nonlinear process models are needed. While in the process industries, nonlinear steady-state models are nowadays available for many processes because they are built and used extensively in the process design phase, there is still a considerable additional effort required to formulate, implement, and validate nonlinear dynamic process models. The effort for rigorous or semi-rigorous modeling usually dominates the cost of an advanced control project. The alternative approach to use black-box or gray-box models as proposed frequently in nonlinear model-predictive control may be effective for regulatory control where the model only has to capture the essential dynamic features of the plant near an operating point, but it seems to be less suitable for optimizing control where the optimal plant performance is aimed at and hence the best stationary values of the inputs and of the controlled variables have to be computed by the controller. As increasingly so-called operator training simulators are built in parallel to the construction of a plant and are continuously used and updated after the commissioning phase, it seems attractive to use the models contained in the simulators also for online optimization. However, the model formulations often are not suitable for this purpose.

Model inaccuracies always have to be taken into account. They not only lead to suboptimal performance but also can cause that the constraints even on measured variables cannot be met in the future because of an insufficient back-off from the constraints. A new approach to deal with uncertainties about model parameters and future influences on the process is multistage scenario-based optimization with recourse. Here the model uncertainties are represented by a set of scenarios of parameter variations and the future availability

of additional information is taken into account. It has been demonstrated that this is an effective tool to handle model uncertainties and to automatically generate the necessary back-off without being overly conservative (Lucia et al. 2013).

State Estimation

For the computation of economically optimal process trajectories based upon a rigorous nonlinear process model, the state variables of the system at the beginning of the prediction horizon must be known. As not all states will be measured in a practical application, state estimation is a key ingredient of a performance optimizing controller. Extended Kalman filters are the standard solution used in the process industries, if the nonlinearities are significant, unscented Kalman filters or particle filters may be used. A novel approach is to formulate the state estimation problem also as an optimization problem on a moving horizon (Rao et al. 2003). The estimation of some important varying unknown model parameters can be included in this formulation. As accurate state estimation is at least as critical for the performance of the closed-loop system as the exact tuning of the optimizing controller, more attention should be paid to the investigation of the performance of state estimation schemes in realistic situations with non-negligible model-plant mismatch.

Stability

Optimization of a cost function over a finite horizon in general neither assures optimality of the complete trajectory beyond this horizon nor stability of the closed-loop system. Closed-loop stability has been addressed extensively in the theoretical research in nonlinear model-predictive control. Stability can be assured by a proper choice of the stage cost within the prediction horizon and the addition of a cost on the terminal state and the restriction of the terminal state to a suitable set. In performance optimizing MPC, there is no a priori known steady state to which the trajectory should converge, and the economic cost function may not satisfy the usual conditions for closed-loop stability, e.g., because it only involves some of the inputs. In recent years, important results on closed-loop stability guaranteeing formulations have nonetheless been obtained, involving terminal constraints or a quasi-infinite horizon (Angeli et al. 2012; Diehl et al. 2011; Grüne 2013).

Reliability and Transparency

Nowadays quite large nonlinear dynamic optimization problems can be solved in real time, not only for slow processes as they are found in the chemical industry but also in mechatronics and automotive control. So this issue does no longer prohibit the application of a performance optimizing control scheme to complex systems. A practically very important limiting issue however is that of reliability and transparency. It is difficult to guarantee that a nonlinear optimizer will provide a solution which at least satisfies the constraints and gives a reasonable performance for all possible input data. While for an RTO scheme an inspection of the commanded set points by the operators usually will be feasible, this is less likely to be realistic in a dynamic situation. Hence, automatic result filters are necessary as well as a backup scheme that stabilizes the process in the case where the result of the optimization is not considered safe. In the process industries, the operators will continue to supervise the operation of the plant in the foreseeable future, so a control scheme that includes performance optimizing control must be structured into modules, the outputs of which can still be understood by the operators so that they build up trust in the optimization. Good operator interfaces that display the predicted moves and the predicted reaction of the plant and enable comparisons with the operators' intuitive strategies are believed to be essential for practical success.

Effort vs. Performance

The gain in performance by a more sophisticated control scheme always has to be traded against the increase in cost due to the complexity of the control scheme – a complex scheme will not only cause cost for its implementation, but it will need more maintenance by better qualified people than a simple one. If a carefully

chosen standard regulatory control layer leads to a close-to-optimal operation, there is no need for optimizing control. If the disturbances that affect profitability and cannot be handled well by the regulatory layer (in terms of economic performance) are slow, the combination of regulatory control and RTO is sufficient. In a more dynamic situation or for complex nonlinear multivariable plants, the idea of direct performance optimizing control should be explored and implemented if significant gains can be realized in simulations.

Modeling of Dynamic Systems from First Principles

S. Torkel Glad
Department of Electrical Engineering,
Linköping University, Linköping, Sweden

Abstract

This entry describes how models can be formed from the basic principles of physics and the other fields of science. Use can be made of similarities between different domains which leads to the concepts of bond graphs and, more abstractly, to port-controlled Hamiltonian systems. The class of models is naturally extended to differential algebraic equation (DAE) models. The concepts described here form a natural basis for parameter identification in gray box models.

Keywords

Introduction

The approach to the modeling of dynamic systems depends on how much is known about the system. When the internal mechanisms are known, it is natural to model them using known relationships from physics, chemistry, biology, etc. Often the result is a model of the following form:

$$\frac{dx}{dt} = f(x, u; \theta), \quad y = h(x, u; \theta) \quad (1)$$

where u is the input, y is the output, and the state x contains internal physical variables, while θ contains parameters. Typically all of these are vectors. The model is known as a state space model. In many cases some elements in θ are unknown and have to be determined using parameter estimation. When used in connection with system identification, these models are sometimes referred to as *gray box* models (in contrast to black box models) to indicate that some degree of physical knowledge is assumed. In ▶ System Identification: An Overview, various connections between physical models and parameter estimation are discussed.

Overview of Physical Modeling

Since modeling covers such a wide variety of physical systems, there are no universal systematic principles. However, a few concepts have wide application. One of them is the preservation of certain quantities like energy, leading to *balance equations.* A simple example is given by the heating of a body. If W is the energy stored as heat, P_1 an external power input, and P_2 the heat loss to the environment per time unit, energy balance gives

$$\frac{dW}{dt} = P_1 - P_2 \quad (2)$$

To get a complete model, one needs also *constitutive relations*, i.e., relations between relevant physical variables. For instance, one might know that the stored energy is proportional to the temperature T, $W = CT$ and that the energy loss is from black body radiation, $P_2 = kT^4$. The model is then
$$C\frac{dT}{dt} = P_1 - kT^4 \quad (3)$$

The model is now an ordinary differential equation with state variable T, input variable P_1 and parameters C and k.

Physical Analogies and General Structures

Physical Analogies

Physicists and engineers have noted that modeling in different areas of physics often gives very similar models. The term "analogies" is

M

Modeling of Dynamic Systems from First Principles, Fig. 1 Electric circuit

Modeling of Dynamic Systems from First Principles, Fig. 2 Mechanical system

often used in modeling to describe this fact. Here we will show some analogies between electrical and mechanical phenomena. Consider the electric circuit given in Fig. 1. An ideal voltage source is connected in series with an inductor, a resistor, and a capacitor. Using u and v to denote the voltages over the voltage source and capacitor, respectively, and i to denote the current, a mathematical model is

$$
C\frac{dv}{dt} = i
$$
$$
L\frac{di}{dt} + Ri + v = u \tag{4}
$$

The first equation uses the definition of capacitance and the second one uses Kirchhoff's voltage law. Compare this to the mechanical system of Fig. 2 where an external force F is applied to a mass m that is also connected to a damper b and a spring with spring constant k. If S is the elongation force of the spring and w the velocity of the mass, a system model is

$$
\frac{dS}{dt} = kw
$$
$$
m\frac{dw}{dt} + bw + S = F \tag{5}
$$

Here the first equation uses the definition of spring constant and the second one uses Newton's 2nd law. The models are seen to be the same with the following correspondences between time-varying quantities

$$
u \leftrightarrow F, \quad i \leftrightarrow w, \quad v \leftrightarrow S \tag{6}
$$

and between parameters

$$
C \leftrightarrow 1/k, \quad L \leftrightarrow m, \quad R \leftrightarrow b \tag{7}
$$

Note that the products (voltage) × (current) and (force) × (velocity) give the power.

Bond Graphs

The bond graph is a tool to do systematic modeling based on the analogies of the previous section. The basic element is the bond

$$
\overset{e}{\underset{f}{\longrightarrow}}
$$

formed by a half arrow showing the direction of positive energy flow. Two variables are associated with the bond, the *effort* variable e and the *flow* variable f. The product ef of these variables gives the power. In the electric domain e is voltage and f is current. For mechanical systems e is force, while f is velocity. Bond graph theory has three basic components to describe storage and dissipation of energy. The relations

$$
\alpha\frac{de}{dt} = f, \quad \beta\frac{df}{dt} = e, \quad \gamma f = e \tag{8}
$$

are known as C, I, and R elements, respectively. Input signals are modeled by elements called effort sources S_e or flow sources S_f, respectively. A bond graph describes the energy flow between these elements. When the energy flow is split, it can either be at s junctions where the flows are equal and the efforts are added or at a p junction where efforts are equal and flows are additive. The model (5), for instance, can be described by the bond graph in Fig. 3. The graph shows how the energy from the external force is split into the acceleration of the mass, the elongation of the spring, and dissipation into the damper. The splitting of the energy flow is accomplished by an s element, meaning that the velocity is the same for all elements but that the forces are added:
Modeling of Dynamic Systems from First Principles, Fig. 3 Bond graph for mechanical or electric system

$$F = N + S + T \qquad (9)$$

Here T and N denote the forces associated with the damper and the mass, respectively. From (8) it follows that

$$k^{-1}\frac{dS}{dt} = w, \quad m\frac{dw}{dt} = N, \quad bw = T \qquad (10)$$

Together (9) and (10) give the same model as (5). Using the correspondences (6), (7) it is seen that the same bond graph can also represent the electric circuit (4). An overview of bond graph modeling is given in Rosenberg and Karnopp (1983). A general overview of modeling, including bond graphs and the connection with identification, can be found in Ljung and Glad (1994b).

Port-Controlled Hamiltonian Systems

Many physical processes can be modeled as Hamiltonian systems. This means that there are state variables x, a scalar function H, and a skew symmetric matrix M so that the system dynamics is

$$\frac{dx}{dt} = M\nabla H(x) \qquad (11)$$

The function H is called the *Hamiltonian* of the system. To be useful in a control context, this model class has to be extended to handle inputs

and dissipation phenomena. To give an example the mechanical system used above is considered again.

Introduce x_1 as the length of the spring so that $dx_1/dt = w$. If H_1 is the energy stored in the spring, then the following relations hold:

$$H_1(x_1) = \frac{kx_1^2}{2}, \quad \frac{\partial H_1}{\partial x_1} = kx_1 = S \qquad (12)$$

Introducing x_2 for the momentum and H_2 as the kinetic energy, one has $dx_2/dt = N$ and

$$H_2(x_2) = \frac{x_2^2}{2m}, \quad \frac{\partial H_2}{\partial x_2} = m^{-1}x_2 = w \qquad (13)$$

Let $H = H_1 + H_2$ be the total energy. Then the following relation holds:

$$\frac{dx}{dt} = \left(\begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} - \begin{bmatrix} 0 & 0 \\ 0 & b \end{bmatrix} \right) \begin{bmatrix} \partial H/\partial x_1 \\ \partial H/\partial x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} F \qquad (14)$$

This model is a special case of

$$\frac{dx}{dt} = (M - R)\nabla H(x) + Bu \qquad (15)$$

where M is a skew symmetric and R a nonnegative definite matrix, respectively. The model type is called a port-controlled Hamiltonian system with dissipation. Without external input ($B = 0$) and dissipation ($R = 0$), it reduces to an ordinary Hamiltonian system of the form (11). For systems generated by simple bond graphs, it can be shown that the junction structure gives the skew symmetric M, while the R elements give the matrix R. The storage of energy in I and C elements is reflected in H. The reader is directed to Duindam et al. (2009) for a description of the port Hamiltonian approach to modeling.

Component-Based Models and Modeling Languages

Since engineering systems are usually assembled from components, it is natural to treat their mathematical models in the same way. This is the idea behind block-oriented models where the output

M

of one model is connected to the input of another one:
A nice feature of this block connection is that the state space description is preserved. Suppose the individual models are of the form (1)

$$\frac{dx_i}{dt} = f_i(x_i, u_i), \quad y_i = h_i(x_i, u_i), \quad i = 1, 2 \tag{16}$$

Then the connection $u_2 = y_1$ immediately gives the state space model

$$\frac{d}{dt}\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} f_1(x_1, u_1) \\ f_2(x_2, h_1(x_1, u_1)) \end{bmatrix}, \tag{17}$$
$$y_2 = h_2(x_2, h_1(x_1, u_1))$$

with input u_1, output y_2, and state $(x_1; x_2)$. This fact is the basis of block-oriented modeling and simulation tools like the MATLAB-based Simulink. Unfortunately the preservation of the state space structure does not extend to more general connections of systems. Consider, for instance, two pieces of rotating machinery described by

$$J_i \frac{d\omega_i}{dt} = -b_i\omega_i + M_i, \quad i = 1, 2 \tag{18}$$

where ω_i is the angular velocity, M_i the external torque, J_i the moment of inertia, and b_i the damping coefficient. Suppose the pieces are joined together so that they rotate with the same angular velocity. The mathematical model would then be

$$J_1 \frac{d\omega_1}{dt} = -b_1\omega_1 + M_1$$
$$J_2 \frac{d\omega_2}{dt} = -b_2\omega_2 + M_2 \tag{19}$$
$$\omega_1 = \omega_2$$
$$M_1 = -M_2$$

This is no longer a state space model of the form (1), but a mixture of dynamic and static relationships, usually referred to as a differential

algebraic equation (DAE). The difference from the connection of blocks in block diagrams is that now the connection is not between an input and an output. Instead there are the equations $\omega_1 = \omega_2$ and $M_1 = -M_2$ that destroy the state space structure. There exist modeling languages like Modelica (Fritzson 2000; Tiller 2001) or SimMechanics in MATLAB (MathWorks 2002) that accept this more general type of model. It is then possible to form model libraries of basic components that can be interconnected in very general ways to form models of complex systems. However, this more general structure poses some challenges when it comes to analysis and simulation that are described in the next section.

Differential Algebraic Equations (DAE)

This model (19) is a special case of the general differential algebraic equation

$$F(dz/dt, z, u) = 0 \tag{20}$$

A good description of both theory and numerical properties of such equations is given in Kunkel and Mehrmann (2006). In many cases it is possible to split the variables and equations in such a way that the following structure is achieved:

$$F(dz_1/dt, z_1, z_2, u) = 0, \quad F_2(z_1, z_2, u) = 0 \tag{21}$$

If z_2 can be solved from the second equation and substituted into the first one, and if dz_1/dt can then be solved from the first equation, the problem is reduced to an ordinary differential equation in z_1. Often, however, the situation is not as simple as that. For the example (19) an addition of the first two equations gives

$$(J_1 + J_2)\frac{d\omega_1}{dt} = -(b_1 + b_2)\omega_1 \tag{22}$$

which is a standard first-order system description. Note, however, that in order to arrive at this result, the relation $\omega_1 = \omega_2$ has to be differentiated. This DAE thus includes an implicit differentiation.

In the general case one can investigate how many times (20) has to be differentiated in order to get an explicit expression for dz/dt. This number is called the (differentiation) index. Both theoretical analysis and practical experience show that the numerical difficulties encountered when solving a DAE increase with increasing index; see, e.g., the classical reference Brenan et al. (1987). It turns out that mechanical systems in particular give high-index models when constructed by joining components, and this has been an obstacle to the use of DAE models. For linear DAE models the role of the index can be seen more easily. A linear model is given by

$$E\frac{dz}{dt} + Fz = Gu \qquad (23)$$

where the matrix E is singular (if E is invertible, multiplication with E^{-1} from the left gives an ordinary differential equation). The system can be transformed by multiplying with P from the left and changing variables with $z = Qw(P, Q$ nonsingular matrices). The transformed model is now

$$PEQ\frac{dw}{dt} + PFQw = PGu \qquad (24)$$

If $\lambda E + F$ is nonsingular for some value of the scalar λ, then it can be shown that there is a choice of P and Q such that (24) takes the form

$$\begin{bmatrix} I & 0 \\ 0 & N \end{bmatrix} \begin{bmatrix} dw_1/dt \\ dw_2/dt \end{bmatrix} + \begin{bmatrix} -A & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} w_1 \\ w_2 \end{bmatrix} = \begin{bmatrix} B_1 \\ B_2 \end{bmatrix} u \qquad (25)$$

where N is a nilpotent matrix, i.e., $N^k = 0$ for some positive integer k. The smallest such k turns out to be the index of the DAE. The transformed model (25) thus contains an ordinary differential equation:

$$\frac{dw_1}{dt} = Aw_1 + B_1u \qquad (26)$$

Using the nilpotency of N, the equation for w_2 can be rewritten:

$$w_2 = B_2u - NB_2\frac{du}{dt} + \cdots + (-N)^{k-1}B_2\frac{d^{k-1}u}{dt^{k-1}} \qquad (27)$$

This expression shows that an index $k > 1$ implies differentiation of the input (unless $N\,B_2$ happens to be zero). This in turn implies potential difficulties, e.g., if u is a measured signal.

Identification of DAE Models

The extended use of DAE models in modern modeling tools also means that there is a need to use these models in system identification. To fully use system identification theory, one needs a stochastic model of disturbances. The inclusion of such disturbances leads to a class of models described as stochastic differential algebraic equations. The treatment of such models leads to some interesting problems. In the previous section it was seen that DAE models often contain implicit differentiations of external signals. If a DAE model is to be well posed, this differentiation must not affect signals modeled as white noise. In Gerdin et al. (2007), conditions are given that guarantee that stochastic DAEs are well posed. There it is also described how a maximum likelihood estimate can be made for DAE models, laying the basis for parameter estimation.

Differential Algebra

For the case where models consist of polynomial equations, it is possible to manipulate them in a very systematic way. The model (20) is then generalized to

$$F(d^nz/dt^n, \ldots, dz/dt, z) = 0 \qquad (28)$$

where z is now a vector containing an arbitrary mix of inputs, outputs, and internal variables. There is then a theory based on Ritt (1950) that allows the transformation of (28) to a standard form where the properties of the system can be easily determined. The process is similar to the use of Gröbner bases but also includes the possibility of differentiating equations. Of particular interest to identification is the possibility of determining the identifiability of parameters with these tools. The model is then of the form

$$\begin{aligned} F(d^my/dt^m, \ldots, dy/dt, y, d^nz/dt^n, \\ \ldots, dz/dt, z; \theta) = 0 \end{aligned} \qquad (29)$$

where y contains measured signals, z contains unmeasured variables, and θ is a vector of parameters to be identified, while F is a vector of polynomials in these variables. It was shown in Ljung and Glad (1994a) that there is an algorithm giving for each parameter θ_k a polynomial:

$$g_k(d^m y/dt^m, \ldots, dy/dt, y; \; \theta_k) = 0 \quad (30)$$

This relation can be regarded as a polynomial in θ_k where all coefficients are expressed in measured quantities. The local or global identifiability will then be determined by the number of solutions. If θ_k is unidentifiable, then no equation of the form (30) will exist, and this fact will also be demonstrated by the output of the algorithm.

Summary and Future Directions

There is no general method to derive models from first principles. However, modeling techniques based on bond graphs or port-controlled Hamiltonian systems offer a systematic approach for large model classes. Modeling languages like Modelica make the practical work with modeling much easier. A fundamental problem that comes up is that models are not necessarily in state space form but are so called differential algebraic equation (DAE) models. Much of the future work is expected to deal with the handling of DAE models and in the development of modeling languages.

Modeling, Analysis, and Control with Petri Nets

Manuel Silva
Instituto de Investigación en Ingeniería de Aragón (I3A), Universidad de Zaragoza, Zaragoza, Spain

Abstract

Petri net is a generic term used to designate a broad family of related formalisms for discrete event views of (dynamic) Systems (DES), all

sharing some basic relevant features, such as *minimality* in the number of primitives, *locality* of the states and actions (with consequences for model construction), or *temporal realism*. The global state of a system is obtained by the juxtaposition of the different local states. We should initially distinguish between *autonomous* formalisms and those *extended by interpretation*. Models in the latter group are obtained by restricting the underlying autonomous behaviors by means of constraints that can be related to different kinds of external events, in particular to time. This article first describes *place/transition* nets (PT-nets), by default simply called Petri nets (PNs). Other formalisms are then mentioned. As a system theory modeling paradigm for concurrent DES, Petri nets are used in a wide variety of application fields.

Keywords

Condition/event nets (CE-nets); Continuous Petri nets (CPNs); Diagrams; Fluidization; Grafcet; Hybrid Petri nets (HPNs); Marking Petri nets; Place/transition nets (PT-nets); High-level Petri nets (HLPNs)

Introduction

Petri nets (PNs) are able to model concurrent and distributed DES (▶ Models for Discrete Event Systems: An Overview). They constitute a powerful family of formalisms with different expressive purposes and power. They may be applied to inter alia, modeling, logical analysis, performance evaluation, parametric optimization, dynamic control (minimum makespan, supervisory control, or other kinds), diagnosis, and implementation issues (eventually fault tolerant). Hybrid and continuous PNs are particularly useful when some parts of the system are highly populated. Being *multidisciplinary*, formalisms belonging to the Petri nets paradigm may cover several phases of the life cycle of complex DES.

A Petri net can be represented as a bipartite directed graph provided with arcs inscriptions; alternatively, this structure can be represented in algebraic form using some matrices. As in the case of differential equations, an initial condition or state should be defined in order to represent a dynamic system. This is done by means of an initial distributed state. The English translation of the Carl Adam Petri's seminal work, presented in 1962, is Petri (1966).

Untimed Place/Transition Net Systems

A place/transition net (PT-net) can be viewed as $\mathcal{N} = \langle P, T, \textbf{\textit{Pre}}, \textbf{\textit{Post}} \rangle$, where:

- P and T are disjoint and finite nonempty sets of *places* and *transitions*, respectively.
- **Pre** and **Post** are $|P| \times |T|$ sized, natural-valued (zero included), incidence matrices. The net is said to be *ordinary* if **Pre** and **Post** are valued on $\{0, 1\}$. Weighted arcs permit the abstract modeling of *bulk* services and arrivals.

A PT-net is a structure. The **Pre (Post)** function defines the connections from places to transitions (transitions to places). Those two functions can alternatively be defined as *weighted flow* relations (nets as graphs). Thus, PT-nets can be represented as *bipartite directed graphs* with *places* (p, using circles) and *transitions* (t, using bars or rectangles) as nodes: $\mathcal{N} = \langle P, T, F, W \rangle$, where $F \subseteq (P \times T) \cup (T \times P)$ is the *flow relation* (set of directed arcs, with $dom(F) \cup range(F) = P \cup T$), and $W : F \rightarrow \mathbb{N}^+$ assigns a natural weight to each arc.

The net structure represents the *static* part of the DES model. Furthermore, a "distributed state" is defined over the set of places, known as the *marking*. This is "numerically quantified" (not in an arbitrary alphabet, as in automata), associating *natural* values to the local state variables, the places. If a place p has a value $\upsilon(m(p) = \upsilon)$, it is said to have υ *tokens* (frequently depicted in graphic terms with υ black dots or just the number inside the place). The places are "state variables," while the markings are their "values"; the *global state* is defined through the concatenation of local states. The net structure, provided with an initial

M
Modeling, Analysis, and Control with Petri Nets, Fig. 1 Most basic PN constructions: The logical OR is present around places, in *choices* (or branches) and *attributions* (or meets); the logical AND is formed around transitions, in *joins* (or waits or *rendezvous*) and *forks* (or splits)
Modeling, Analysis, and Control with Petri Nets, Fig. 2 Only transitions *b* and *c* are initially enabled. The results of firing *b* or *c* are shown subsequently

marking, to be denoted as $(\mathcal{N}, m_0)$, is a *Petri net system*, or *marked Petri net*.

The last two basic PN constructions in Fig. 1 (*join* and *fork*) do not appear in finite-state machines; moreover, the arcs may be valued with natural numbers. The dynamic behavior of the net system (trajectories with changes in the marking) is produced by the firing of transitions, some "local operations" which follows very simple rules.

Markings in net systems evolve according to the following *firing* (or *occurrence*) rules (see, Fig. 2):

- A transition is said to be *enabled* at a given marking if each input place has at least as many tokens as the weight of the arc joining them.
- The *firing* or *occurrence* of an enabled transition is an instantaneous operation that removes from (adds to) each input (output) place a number of tokens equal to the weight of the arc joining the place (transition) to the transition (place).

The precondition of a transition can be seen as the resources required for the transition to be fired. The weight of the arc from a place to a transition represents the number of resources to be *consumed*. The post-condition defines the number resources *produced* by the firing of the transition. This is made explicit by the weights of the arcs from the transition to the places. Three important observations should be taken into account:

- The underlying logic in the firing of a transition is non-monotonic! It is a *consumption/production* logic.
- Enabled transitions are never *forced* to fire: This is a form of *non-determinism*.
- An *occurrence sequence* is a sequence of fired transitions $\sigma = t_1 \ldots t_k$. In the evolution from m_0, the reached marking m can be easily computed as:

$$m = m_0 + C \cdot \sigma, \qquad (1)$$

where $C = Post - Pre$ is the *token flow* matrix (*incidence* matrix if $\mathcal{N}$ is self-loop free) and σ the firing count vector corresponding to σ. Thus m and σ are vectors of natural numbers.

The previous equation is the *state-transition* equation (frequently known as the *fundamental* or, simply, *state* equation). Nevertheless, two important remarks should be made:

- It represents a necessary but not sufficient condition for reachability; the problem is that the existence of a $\boldsymbol{\sigma}$ does not guarantee that a corresponding sequence σ is firable from $\boldsymbol{m}_0$; thus, certain solutions – called *spurious* (Silva et al. 1998) – are not reachable. This implies that – except in certain net system subclasses – only semi-decision algorithms can usually be derived.
- All variables are natural numbers, which imply computational complexity.

It should be pointed out that in finite-state machines, the state is a single variable taking values in a symbolic unstructured set, while in PT-net systems, it is structured as a vector of nonnegative integers. This allows analysis techniques that do not require the enumeration of the state space.

At a structural level, observe that the negation is missing in Fig. 1; its inclusion leads to the so-called *inhibitor arcs*, an extension in expressive power. In its most basic form, if the place at the origin of an inhibitor arc is marked, it "inhibits" the enabling of the target transition. PT-net systems can model infinite-state systems, but not Turing machines. PT-net systems provided with inhibitor arcs (or *priorities* on the firing of transitions) can do it.

With this conceptually simple formalism, it is not difficult to express basic synchronization schemas (Fig. 3). All the illustrated examples use *joins*. When *weights* are allowed in the arcs, another kind of synchronization appears: Several copies of the same resource are needed (or produced) in a single operation. Being able to express *concurrency* and *synchronization*, when viewing the system at a higher level, it is possible to build *cooperation* and *competition* relationships.

Analysis and Control of Untimed PT Models

The behavior of a concurrent (eventually distributed) system is frequently difficult to understand and control. Thus, misunderstandings and mistakes are frequent during the design cycle. A way of cutting down the cost and duration of the

design process is to express in a formalized way properties that the system should enjoy and to use formal proof techniques. Errors can be eventually detected close to the moment they are introduced, reducing their propagation to subsequent stages. The goal in *verification* is to ensure that a given system is correct with respect to its specification (perhaps expressed in temporal-logic terms) or to a certain set of predetermined properties.

Among the most basic qualitative properties of "net systems" are the following: (1) *reachability* of a marking from a given one; (2) *boundedness*, characterizing finiteness of the state space; (3) *liveness*, related to potential fireability of all transitions starting on an arbitrary reachable marking (*deadlock-freeness* is a weaker condition in which only global infinite fireability of the net system model is guaranteed, even if some transitions no longer fire); (4) *reversibility*, characterizing recoverability of the initial marking from any reachable one; and (5) *mutual exclusion of two places*, dealing with the impossibility of reaching markings in which both places are simultaneously marked.

All the above are *behavioral* properties, which depend on the net system ($\mathcal{N}, \boldsymbol{m}_0$). In practice, sometimes problems with a net model are rooted in the net structure; thus, the study of the *structural* counterpart of certain behavioral properties may be of interest. For example, a "net" is *structurally bounded* if it is bounded for any initial marking; a "net" is *structurally live* if an initial marking exists that make the net system live (otherwise stated, it reflect non-liveness for arbitrary initial markings, a pathology of the net).

Basic techniques to analyze net systems include: (1) *enumeration*, in its most basic form based on the construction of a *reachability graph* (a sequentialized view of the behavior). If the net system is not bounded, losing some information, a finite *coverability graph* can be constructed; (2) *transformation*, based on an iterative rewriting process in which a net system enjoys a certain property if and only if a transformed ("simpler" to analyze) one also does. If the new system is easier to analyze, and the transformation is computationally cheap, the process may be extremely interesting; (3) *structural*, based on
Modeling, Analysis, and Control with Petri Nets, Fig. 3 Basic synchronization schemes: (*1*) Join or *rendezvous, RV*; (*2*) *Semaphore, S*; (*3*) Mutual exclusion semaphore (*mutex*), R, representing a shared resource; (*4*) Symmetric RV built with two semaphores; (*5*) Asymmetric RV built with two semaphores (*master/slave*); (*6*) Fork-join (or *par-begin/par-end*); (*7*) Non-recursive *subprogram* (places *i* and *j* cannot be simultaneously marked – must be in mutex – to remember the returning point; for simplicity, it is assumed that the subprogram is single input/single output); (*8*) Guard (a self-loop from a place through a transition); its role is like a traffic light: If at least one token is present at the place, it allows the evolution, but it is not consumed. Synchronizations can also be modeled by the weights associated to the arcs going to transitions

graph properties, or in mathematical programming techniques rooted on the state equation; (4) *simulation*, particularly interesting for gaining certain confidence about the absence of certain pathological behaviors. Analysis strategies combining all these kinds of techniques are extremely useful in practice.

Reachability techniques provide sequentialized views for a particular initial marking. Moreover they suffer from the so-called *state explosion* problem. The reduction of this computational issue leads to techniques such as *stubborn set* methods (smaller, equally informative reachability graphs), also to non-sequentialized views such as those based on *unfoldings*. Transformation techniques are extremely useful, but not complete (i.e., not all net systems can be reduced in a practical way). In most cases, structural techniques only provide necessary or sufficient conditions (e.g., a sufficient condition for deadlock-freeness, a necessary condition for reversibility, etc.), but not a full characterization. As already pointed out, a limitation of methods based on the state equation for analyzing net systems is the existence of non reachable solutions (the so-called *spurious solutions*). In

this context, three kinds of related notions that must be differentiated are the following: (1) some natural vectors (left and right annullers of the token flow matrix, C: *P-semiflows* and *T-semiflows*), (2) some invariant laws (*token conservation* and *repetitive behaviors*), and (3) some peculiar subnets (*conservative* and *consistent* components, generated by the subsets of nodes in the P- and T-semiflows, respectively).

More than analysis, *control* leads to synthesis problems. The idea is *to enforce* the given system in order to fulfill a specification (e.g., to enforce certain mutual exclusion properties). Technically speaking, the idea is to "add" some elements in order to constrain the behavior in such a way that a correct execution is obtained. Questions related to control, observation, diagnosis, or identification are all areas of ongoing research.

With respect to classical control theory, there are two main differences: Models are DES and untimed (autonomous, fully nondeterministic, eventually labeling the transitions in order to be able to consider the PNs languages). Let us remark that for control purposes, the transitions should be partitioned into *controllable* (when enabled, you can either force or block the firing) and *uncontrollable* (if enabled, the firing is nondeterministic). A natural approach to synthesize a control is to start modeling the plant dynamics (by means of a PN, P) and adopting a specification for the desired closed-loop system (S). The goal is to compute a controller (L) such that S equals the parallel-composition of P and L; in other words, controllers (called "supervisors") are designed to ensure that only behaviors consistent with the specification may occur. The previous equality is not always possible, and the goal is usually relaxed to minimally limit the behavior within the specified legality (i.e., to compute *maximally permissive* controllers). For an approach in the framework of finite-state machines and regular languages, see ▸ Supervisory Control of Discrete-Event Systems. The synthesis in the framework of Petri nets and having goals as enforcing some generalized mutual exclusions constraints in markings or avoiding deadlocks, for example, can be efficiently approached by means of the

so named *structure theory*, based on the direct exploitation of the structure of the net model (using graph or mathematical programming theories and algorithms, where the initial marking is a parameter).

Similarly, transitions (or places) can be partitioned into *observable* and *unobservable*. Many *observability* problems may be of interest; for example, observing the firing of a subset of transitions to compute the subset of markings in which the system may be. Related to observability, *diagnosis* is the process of detecting a failure (any deviation of a system from its intended behavior) and identifying the cause of the abnormality. *Diagnosability*, like observability or controllability, is a logical criterion. If a model is diagnosable with respect to a certain subset of possible faults (i.e., it is possible to detect the occurrence of those faults in finite time), a diagnoser can be constructed (see section "Diagnosis and Diagnosability Analysis of Petri Nets" in ▸ Diagnosis of Discrete Event Systems). *Identification* of DES is also a question that has required attention in recent years. In general, the starting point is a behavioral observation, the goal being to construct a PN model that generates the observed behavior, either from examples/counterexamples of its language or from the structure of a reachability graph. So the results are *derived* models, not human-made models (i.e., not made by designers).

The Petri Nets Modeling Paradigm

Along the *life cycle* of DES, designers may deal with basic modeling, analysis, and synthesis from different perspectives together with implementation and operation issues. Thus, the designer may be interested in expressing the basic structure, understanding untimed possible behaviors, checking logic properties on the model when provided with some timing (e.g., in order to guarantee if a certain reaction is possible before 3 ms; something relevant in real-time systems), computing some performance indices on timed models (related to the throughput in the firing of a given transition, or to the length of a waiting line,

expressed as the number of tokens in a place), computing a schedule or control that optimizes a certain objective function, decomposing the model in order to prepare an efficient implementation, efficiently determining redundancies in order to increase the degree of fault tolerance, etc. For these different tasks, different formalisms may be used. Nevertheless, it seems desirable to have a *family* of related formalisms rather than a collection of "unrelated" or weakly related formalisms. The expected advantages would include *coherence* among models usable in different phases, *economy* in the transformations and *synergy* in the development of models and theories.

Other Untimed PN Formalisms: Levels of Expressive Power

PT-net systems are more powerful than *condition/event* (CE) systems, roughly speaking the basic seminal formalism of Carl Adam Petri in which places can be marked only with zero or one token (Boolean marking). CE-systems can model only finite-state systems. As already said, "extensions" of the expressive power of untimed PT-net systems to the level of Turing machines are obtained by adding inhibitor arcs or priorities to the firing of transitions.

An important idea is adding the notion of *individuals* to tokens (e.g., from anonymous to labeled or colored tokens). Information in tokens allows the objects to be named (they are no longer indistinguishable) and dynamic associations to be created. Moving from PT-nets to so-called *high-level PNs* (HLPNs) is something like "moving from assembler to high-level programming languages," or, at the computational level, like "moving from pure numerical to a symbolic level." There are many proposals in this respect, the more important being predicate/transition nets and colored PNs. Sometimes, this type of abstraction has the same theoretical expressiveness as PT-net systems (e.g., colored PNs if the number of colors is finite); in other words, high-level views may lead to more compact

and structured models, while keeping the same theoretical expressive power of PT-nets (i.e., we can speak of "abbreviations," not of "extensions"). In other cases, *object-oriented* concepts from computer programming are included in certain HLPNs. The analysis techniques of HLPNs can be approached with techniques based on enumeration, transformation, or structural considerations and simulation, generalizing those developed for PT-net systems.

Extending Net Systems with External Events and Time: Nonautonomous Formalisms

When dealing with net systems that interact with some specific environment, the marking evolution rule must be slightly modified. This can be done in an enormous number of ways, considering external events and logical conditions as inputs to the net model, in particular some depending on time. The same interpretation given to a graph in order to define a finite-*state diagram* can be used to define a *marking diagram*, a formalism in which the key point is to recognize that the state is now numerical (for PT-net systems) and distributed. For example, drawing a parallel with Moore automata, the transitions should be labeled with logical conditions and events, while unconditional actions are associated to the places. If a place is marked, the associated actions are emitted.

Even if only *time-based interpretations* are considered, there are a large number of successful proposals for formalisms. For example, it should be specified if time is associated to the firing of transitions (T-timing may be atomic or in three phases), to the residence of tokens in places (P-timed), to the arcs of the net, as tags to the tokens, etc. Moreover, even for T-timed models, there are many ways of defining the timing: *time intervals*, *stochastic* or *possibilistic* forms, and the *deterministic* case as a particular one. If the firing of transitions follows *exponential* pdfs, and the conflict resolution follows the *race* policy (i.e., fire in conflicts the first that ends the task,

not a *preselection* policy), the underlying Markov chain described is isomorphic to the reachability graph (due to the Markovian "memoryless" property). Moreover, the addition of *immediate* transitions (whose firing is instantaneous) enriches the practical modeling possibilities, eventually complicating the analysis techniques. Timed models are used to compute minimum and maximum time delays (when time intervals are provided, in real-time problems) or performance figures (throughput, utilization rate of resources, average number of tokens – clients – in services, etc.). For performance evaluation, there is an array of techniques to compute bounds, approximated values, or exact values, sometimes generalizing those that are used in certain queueing network classes of models. Simulation techniques are frequently very helpful in practice to produce an *educated guess* about the expected performance.

Time constraints on Petri nets may change logical properties of models (e.g., mutual exclusion constraints, deadlock-freeness, etc.), calling for new analysis techniques. For example, certain timings on transitions can transform a live system into a non-live one (if to the net system in Fig. 2 are associated deterministic times to transitions and a race policy with the time associated to transition *c* smaller than that of transition *a*, transition *b* cannot be fired, after firing transition *d*; thus it is non-live, while the untimed model was live). By the addition of some time constraints, the transformation of a non-live model into a live one is also possible. So additional analysis techniques need to be considered, redefining the state, now depending also on time, more than just on the marking.

Finally, as in any DES, the optimal control of timed Petri net models (scheduling, sequencing, etc.) may be approached by techniques as dynamic programming or perturbation analysis (presented in the context of queueing networks and Markov chains, see ▶ Perturbation Analysis of Discrete Event Systems). In practice, those problems are frequently approached by means of some partially heuristic strategies. About the diagnosis of timed Petri nets, see ▶ Diagnosis of Discrete Event Systems. Of course, all these tasks can be done with HLPNs.

Fluid and Hybrid PN Models

Different ideas may lead to different kinds of *hybrid* PNs. One is to *fluidize* (here to relax the natural numbers of discrete markings into the nonnegative reals) the firing of transitions that are "most time" enabled. Then the relaxed model has *discrete* and *continuous* transitions, thus also *discrete* and *continuous* places. If all transitions are fluidized, the PN system is said to be *fluid* or *continuous*, even if technically it is a hybrid one. In this approach, the main goal is to try to overcome the *state explosion* problem inherent to enumeration techniques. Proceeding in that way, some computationally NP-hard problems may become much easier to solve, eventually in polynomial time. In other words, *fluidization* is an abstraction that tries to make tractable certain real-scale DES problems (▶ Discrete Event Systems and Hybrid Systems, Connections Between).

When transitions are timed with the so-called *infinite server* semantics, the PN system can be observed as a time differentiable *piecewise affine system*. Thus, even if the relaxation "simplifies" computations, it should be taken into account that continuous PNs with infinite server semantics are able to simulate Turing machines. From a different perspective, the steady-state throughput of a given transition may be non-monotonic with respect to the firing rates or the initial marking (e.g., if faster or more machines are used, the uncontrolled system may be slower); moreover, due to the important expressive power, *discontinuities* may even appear with respect to continuous design parameters as firing rates, for example.

An alternative way to define hybrid Petri nets is a generalization of *hybrid automata*: The net system is a DES, but sets of differential equations are associated to the marking of places. If a place is marked, the corresponding differential equations contribute to define its evolution.

Summary and Future Directions

Petri nets designate a broad family of related DES formalisms (a modeling paradigm) each one specifically tailored to approach certain problems. Conceptual simplicity coexists with

powerful modeling, analysis, and synthesis capabilities. From a control theory perspective, much work remains to be done for both untimed and timed formalisms (remember, there are many different ways of timing), particularly when dealing with optimal control of timed models. In engineering practice, approaches to the latter class of problems frequently use heuristic strategies. From a broader perspective, future research directions include improvements required to deal with controllability and the design of controllers, with observability and the design of observers, with diagnosability and the design of diagnosers, and with identification. This work is not limited to the strict DES framework, but also applies to analogous problems relating to relaxations into *hybrid* or *fluid* approximations (particularly useful when high populations are considered). The distributed nature of system is more and more frequent and is introducing new constraints, a subject requiring serious attention. In all cases, different from firing languages approaches, the so named *structure theory* of Petri nets should gain more interest.

Recommended Reading

Topics related to PNs are considered in well over a hundred thousand papers and reports. The first generation of books concerning this field is Brauer (1980), immediately followed by Starke (1980), Peterson (1981), Brams (1983), Reisig (1985), and Silva (1985). The fact that they are written in English, French, German, and Spanish is proof of the rapid dissemination of this

knowledge. Most of these books deal essentially with PT-net systems. Complementary surveys are Murata (1989), Silva (1993), and David and Alla (1994), the latter also considering some continuous and hybrid models. Concerning high-level PNs, Jensen and Rozenberg (1991) is a selection of papers covering the main developments during the 1980s. Jensen and Kristensen (2009) focuses on state space methods and simulation where elements of timed models are taken into account, but performance evaluation of stochastic systems is not covered. Approaching the present day, relevant works written with complementary perspectives include inter alia, Girault and Valk (2003), Diaz (2009), David and Alla (2010), and Seatzu et al. (2013). The consideration of time in nets with an emphasis on performance and performability evaluation is addressed in monographs such as Ajmone Marsan et al. (1995), Bause and Kritzinger (1996), Balbo and Silva (1998), and Haas (2002), while timed models under different fuzzy interpretations are the subject of Cardoso and Camargo (1999). Structure-based approaches to controlling PN models is the main subject in Iordache and Antsaklis (2006) or Chen and Li (2013). Different kinds of hybrid PN models are studied in Di Febbraro et al. (2001), Villani et al. (2007), and David and Alla (2010), while a broad perspective about modeling, analysis, and control of continuous (untimed and timed) PNs is provided by Silva et al. (2011).

DiCesare et al. (1993) and Desrochers and Al-Jaar (1995) are devoted to the applications of PNs to manufacturing systems. A comprehensive updated introduction to business process systems and PNs can be found in van der Aalst and Stahl (2011). Special volumes dealing with other monographic topics are, for example, Billington et al. (1999), Agha et al. (2001), and Cortadella et al. (2002). An application domain for Petri nets emerging over the last two decades is *systems biology*, a model-based approach devoted to the analysis of biological systems (Koch et al. 2011; Wingender 2011). Furthermore, it should be pointed out that Petri nets have also been employed in many other application domains (e.g., from logistics to musical systems).

For an overall perspective of the field over the five decades that have elapsed since the publication of Carl Adam Petri's PhD thesis, including historical, epistemological, and technical aspects, see Silva (2013).

MPC

Abstract

This entry provides a brief description of model
predictive control (MPC) technology and how it
is used in practice. The emphasis here is on re-
fining and chemical plant applications where the
technology has achieved its greatest acceptance.
After a short description of what MPC is and
how it fits into the hierarchy of control functions,
the basic algorithm is presented as a sequence of
three optimization problems. The steps required
for a successful application are then outlined,
followed by a summary and outline of likely
future directions for MPC technology.

Keywords

Computer control; Mathematical programming;
Predictive control

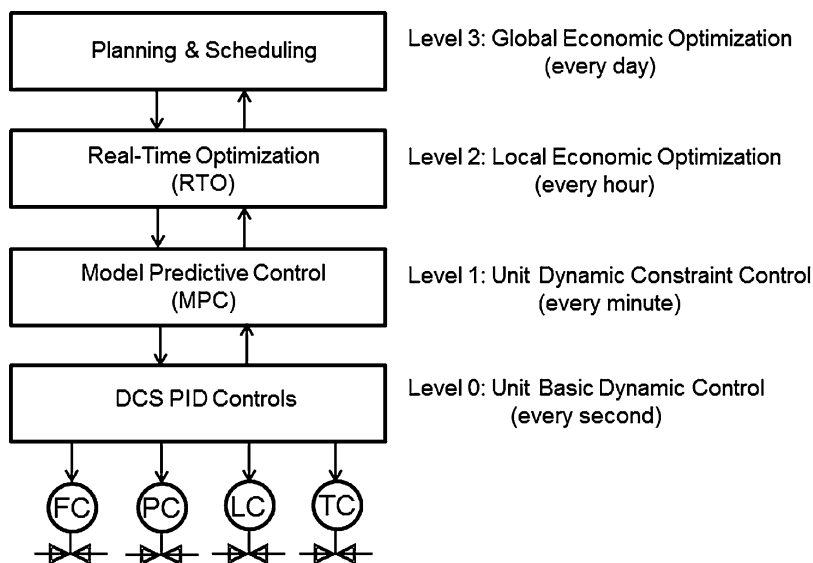
Introduction

Model predictive control (MPC) refers to a class
of computer control algorithms that utilize an
explicit mathematical model to predict future
process behavior. At each control interval, in the
most general case, an MPC algorithm solves a
sequence of three nonlinear programs to answer
the following essential questions: where is the
process heading (state estimation), where should
the process go (steady-state target optimization),
and what is the best sequence of control (input)
adjustments to send it to the right place (dynamic
optimization). The first control (input) adjust-
ment is implemented and then the entire cal-
culation sequence is repeated at the subsequent
control cycles.

MPC technology arose first in the context of
petroleum refinery and power plant control prob-
lems (Cutler and Ramaker 1979; Richalet et al.
1978). Specific needs that drove the development
of MPC technology include the requirement for
economic optimization and strict enforcement
of safety and equipment constraints. Promising
early results led to a wave of successful industrial
applications, sparking the development of several
commercial offerings (Qin and Badgwell 2003)
and generating intense interest from the academic
community (Mayne et al. 2000). Today MPC
technology permeates the refining and chemical
industries and has gained increasing acceptance
in a wide variety of areas including chemicals,
automotive, aerospace, and food processing ap-
plications. The total number of MPC applications
worldwide was estimated in 2003 to be 4,500
(Qin and Badgwell 2003).

MPC Control Hierarchy

In a modern chemical plant or refinery, MPC
is part of a multilevel hierarchy, as illustrated
in Fig. 1. Moving from the top level to the
bottom, the control functions execute at a
higher frequency but cover a smaller geographic
scope. At the bottom level, referred to as
Level 0, proportional-integral-derivative (PID)
controllers execute several times a second within
distributed control system (DCS) hardware.
These controllers adjust individual valves to
maintain desired flows, pressures, levels, and
temperatures.

At Level 1, MPC runs once a minute
to perform dynamic constraint control for
an individual processing unit, such as crude
distillation unit or a fluid catalytic cracker (Gary
et al. 2007). It typically utilizes a linear dynamic


Model-Predictive Control in Practice, Fig. 1 Hierarchy of control functions in a refinery/chemical plant

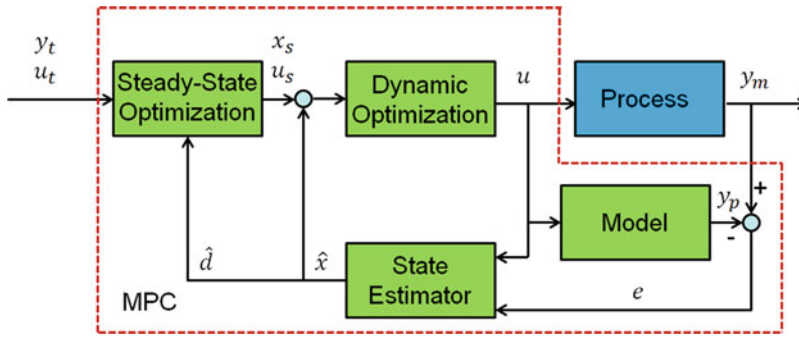
model identified directly from process step-test data. The MPC has the job of holding the unit at the best economic operating point in the face of dynamic disturbances and operational constraints.

At Level 2, a real-time optimizer (RTO) runs hourly to calculate optimal steady-state targets for a collection of processing units. It uses a rigorous first-principles steady-state model to calculate targets for key operating variables such as unit temperatures and feed rates. These are typically passed down to several MPCs for implementation.

At Level 3, planning and scheduling functions are carried out daily to optimize economics for an entire chemical plant or refinery. Simple steady-state models are typically used at this level, with some nonlinear but mostly linear connections between model inputs and outputs. Key operating targets and economic data are typically passed to several RTO applications for implementation.

Note that a different mathematical model of the process is used at each level of the hierarchy. These models must be reconciled in some manner with current plant operation and with each other in order for the overall system to function properly.

MPC Algorithms

MPC algorithms function in much the same way that an experienced human operator would approach a control problem. Figure 2 illustrates the flow of information for a typical MPC implementation. At each control interval, the algorithm compares the current model output prediction y_p to the measured output y_m and passes the prediction error e and control (input) u to a state estimator, which estimates the dynamic state x. The most commonly used methods for state estimation can be viewed as special cases of an optimization-based formulation called moving horizon estimation (MHE) (Rawlings and Mayne 2009). The state estimate $\hat{x}$, which includes an estimate of the process disturbances $\hat{d}$, is then passed to a steady-state optimizer to determine the best operating point for the unit. The steady-state optimizer must also consider operator-entered output and control (input) targets y_t and u_t. The steady-state state and control (input) targets x_s and u_s are then passed, along with the state estimate $\hat{x}$, to a dynamic optimizer to compute the best trajectory of future control (input) adjustments. The first computed control (input) adjustment is then implemented and the entire calculation sequence is repeated at the


Model-Predictive Control in Practice, Fig. 2 Information flow for MPC algorithm

next control interval. The various commercial MPC algorithms differ in such details as the mathematical form of the dynamic model and the specific formulations of the state estimation, steady-state optimization, and dynamic optimization problems (Qin and Badgwell 2003).

In the general case, the MPC algorithm must solve the three optimization problems outlined above at each control interval. For the case of linear models and reasonable tuning parameters, these problems take the form of a convex quadratic program (QP) with a constant, positive-definite Hessian. As such, they can be solved relatively easily using standard optimization codes. For the case of a linear state-space model, the structure can be exploited even further to develop a specialized solution algorithm using an interior point method (Rao et al. 1998).

For the case of nonlinear models, these problems take the form of a nonlinear program (NLP) for which the solution domain is no longer convex, greatly complicating the numerical solution. A typical strategy is to iterate on a linearized version of the problem until convergence (Bielger 2010).

Implementation

The combined experience of thousands of MPC applications in the process industries has led to a near consensus on the steps required for a successful implementation:

- Justification – make the economic case for the application.

- Pre-test – design the control and test sensors and actuators.
- Step-test – generate process response data.
- Modeling – develop model from process response data.
- Configuration – configure the software and test preliminary tuning by simulation.
- Commissioning – turn on and test the controller.
- Post-audit – measure and certify economic performance.
- Sustainment – monitor and maintain the application.

The most expensive of these steps, both in terms of engineering time and lost production, is the generation of process response data through the step test. This is accomplished, in principle, by making significant adjustments to each variable that will be adjusted by the MPC while operating open loop to prevent compensating control action. This will necessarily cause abnormal movement in key operating variables, which may lead to lower throughput and off-spec products. Significant progress has been made in recent years to minimize these difficulties through the use of approximate closed-loop step testing (Darby and Nikolaou 2012).

Once the application has been commissioned, it is critical to set up an aggressive monitoring and sustainment program. MPC application benefits can fall off quickly due to changes in the process operation and as new personnel interact with it. New constraint variables may need to be added and key sections of the model may need

to be updated as time goes on. The mathematical problem of MPC monitoring remains a topic of current academic research (Zagrobelny et al. 2012).

Note that the implementation steps outlined above must be carried out by a carefully selected project team that typically includes, in addition to the MPC expert, an engineer with detailed knowledge of the process and an operator with significant relevant experience.

Summary and Future Directions

Model predictive control is now a mature technology in the process industries. A representative MPC algorithm in this domain includes a state estimator, a steady-state optimizer, and a dynamic optimizer, running once a minute. A successful MPC application usually starts with a careful economic justification, includes significant participation from process engineers and operators, and is maintained with an aggressive sustainment program. Many thousands of such applications are currently operating around the world, generating billions of dollars per year in economic benefits.

Likely future directions for MPC practice include increasing use of nonlinear models, improved state estimation through unmeasured disturbance modeling (Pannocchia and Rawlings 2003), and development of more efficient numerical solution methods (Zavala and Biegler 2009).

Recommended Reading

The first descriptions of MPC technology appear in papers by Richalet et al. (1978) and Cutler

and Ramaker (1979). A detailed summary of the history of MPC technology development, as well as a survey of commercial offerings through 2003 can be found in the review article by Qin and Badgwell (2003). Darby and Nikolaou present a more recent summary of MPC practice (Darby and Nikolaou 2012). Textbook descriptions of MPC theory and design, suitable for classroom use, include Rawlings and Mayne (2009) and Maciejowski (2002). The book by Ljung (1999) provides a good summary of methods for identifying dynamic models from test data. Theoretical properties of MPC are analyzed in a highly cited paper by Mayne and coworkers (2000). Guidelines for designing disturbance models so as to achieve offset-free control can be found in Pannocchia and Rawlings (2003). Numerical solution strategies for the nonlinear programs found in MPC are discussed in the book by Biegler (2010). An efficient interior-point method for solving the linear MPC dynamic optimization is described in Rao et al. (1998). A promising algorithm for solving the nonlinear MPC dynamic optimization is outlined in Zavala and Biegler (2009). A data-based method for tuning Kalman Filters, which are often used for MPC state estimation, is described in Odelson et al. (2006). A new method for monitoring the performance of MPC is summarized in Zagrobelny et al. (2012). A readable summary of refining operations can be found in Gary et al. (2007).

DES

Abstract

This article provides an introduction to discrete event systems (DES) as a class of dynamic systems with characteristics significantly distinguishing them from traditional time-driven systems. It also overviews the main modeling frameworks used to formally describe the operation of DES and to study problems related to their control and optimization.

Keywords

Introduction

Discrete event systems (DES) form an important class of dynamic systems. The term was introduced in the early 1980s to describe a DES in terms of its most critical feature: the fact that its behavior is governed by *discrete events* which occur asynchronously over time and which are solely responsible for generating state transitions. In between event occurrences, the state of a DES is unaffected. Examples of such behavior abound in technological environments, including computer and communication networks, manufacturing systems, transportation systems, logistics, and so forth. The operation of a DES is largely regulated by rules which are often unstructured and frequently human-made, as in initiating or terminating activities and scheduling the use of resources through controlled events (e.g., turning equipment "on"). On the other hand, their operation is also subject to uncontrolled randomly occurring events (e.g., a spontaneous equipment failure) which may or may not be observable through sensors. It is worth pointing out that the term "discrete event dynamic system" (DEDS) is also commonly used to emphasize the importance of the dynamical behavior of such systems (Cassandras and Lafortune 2008; Ho 1991).

There are two aspects of a DES that define its behavior:

1. The variables involved are both continuous and discrete, sometimes purely symbolic, i.e., nonnumeric (e.g., describing the state of a traffic light as "red" or "green"). This renders traditional mathematical models based on differential (or difference) equations inadequate and related methods based on calculus of limited use.

2. Because of the asynchronous nature of events that cause state transitions in a DES, it is neither natural nor efficient to use time as a synchronizing element driving its dynamics.

It is for this reason that DES are often referred to as *event driven*, to contrast them to classical *time-driven* systems based on the laws of physics; in the latter, as time evolves state, variables such as position, velocity, temperature, voltage, etc., also continuously evolve. In order to capture event-driven state dynamics, however, different mathematical models are necessary.

In addition, uncertainties are inherent in the technological environments where DES are encountered. Therefore, associated mathematical models and methods for analysis and control must incorporate such uncertainties. Finally, complexity is also inherent in DES of practical interest, usually manifesting itself in the form of combinatorially explosive state spaces. Although purely analytical methods for DES design, analysis, and control are limited, they have still enabled reliable approximations of their dynamic behavior and the derivation of useful structural properties and provable performance guarantees. Much of the progress made in this field, however, has relied on new paradigms characterized by a combination of mathematical techniques, computer-based tools, and effective processing of experimental data.

Event-driven and time-driven system components are often viewed as coexisting and interacting and are referred to as *hybrid systems* (separately considered in the Encyclopedia, including the article ▶ Discrete Event Systems and Hybrid Systems, Connections Between). Arguably, most contemporary technological systems are combinations of time-driven components (typically, the physical parts of a system) and event-driven components (usually, the computer-based controllers that collect data from and issue commands to the physical parts).

Event-Driven vs. Time-Driven Systems

In order to explain the difference between time-driven and event-driven behavior, we begin with the concept of "event." An event should be thought of as occurring instantaneously and causing transitions from one system state value to another. It may be identified with an action (e.g., pressing a button), a spontaneous natural occurrence (e.g., a random equipment failure), or the result of conditions met by the system state (e.g., the fluid level in a tank exceeds a given value). For the purpose of developing a model for DES, we will use the symbol e to denote an event. Since a system is generally affected by different types of events, we assume that we can define a discrete *event set* E with $e \in E$.

In a classical system model, the "clock" is what drives a typical state trajectory: with every "clock tick" (which may be thought of as an "event"), the state is expected to change, since continuous state variables continuously change with time. This leads to the term *time driven*. In the case of time-driven systems described by continuous variables, the field of systems and control has based much of its success on the use of well-known differential-equation-based models, such as

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t), t), \quad \mathbf{x}(t_0) = \mathbf{x}_0 \quad (1)$$

$$\mathbf{y}(t) = \mathbf{g}(\mathbf{x}(t), \mathbf{u}(t), t), \quad (2)$$

where (1) is a (vector) state equation with initial conditions specified and (2) is a (vector) output equation. As is common in system theory, $\mathbf{x}(t)$ denotes the state of the system, $\mathbf{y}(t)$ is the output, and $\mathbf{u}(t)$ represents the input, often associated with controllable variables used to manipulate the state so as to attain a desired output. Common physical quantities such as position, velocity, temperature, pressure, flow, etc., define state variables in (1). The state generally changes as time changes, and, as a result, the time variable t (or some integer $k = 0, 1, 2, \ldots$ in discrete time) is a natural independent variable for modeling such systems.

In contrast, in a DES, time no longer serves the purpose of driving such a system and may no longer be an appropriate independent variable. Instead, at least some of the state variables are discrete, and their values change only at certain points in time through instantaneous transitions which we associate with "events." If a clock is used, consider two possibilities: (i) At every

M

clock tick, an event e is selected from the event set E (if no event takes place, we use a "null event" as a member of E such that it causes no state change), and (ii) at various time instants (not necessarily known in advance or coinciding with clock ticks), some event e "announces" that it is occurring. Observe that in (i) state transitions are *synchronized* by the clock which is solely responsible for any possible state transition. In (ii), every event $e \in E$ defines a distinct process through which the time instants when e occurs are determined. State transitions are the result of combining these *asynchronous* concurrent event processes. Moreover, these processes need not be independent of each other. The distinction between (i) and (ii) gives rise to the terms *time-driven* and *event-driven* systems, respectively.

Comparing state trajectories of time-driven and event-driven systems is useful in understanding the differences between the two and setting the stage for DES modeling frameworks. Thus, in Fig. 1, we observe the following: (i) For the time-

driven system shown, the state space X is the set of real numbers $\mathbb{R}$, and $x(t)$ can take any value from this set. The function $x(t)$ is the solution of a differential equation of the general form $\dot{x}(t) = f(x(t), u(t), t)$, where $u(t)$ is the input. (ii) For the event-driven system, the state space is some discrete set $X = \{s_1, s_2, s_3, s_4\}$. The sample path can only jump from one state to another whenever an event occurs. Note that an event may take place, but not cause a state transition, as in the case of e_4. There is no immediately obvious analog to $\dot{x}(t) = f(x(t), u(t), t)$, i.e., no mechanism to specify how events might interact over time or how their time of occurrence might be determined. Thus, a large part of the early developments in the DES field has been devoted to the specification of an appropriate mathematical model containing the same expressive power as (1)–(2) (Baccelli et al. 1992; Cassandras and Lafortune 2008; Glasserman and Yao 1994).

We should point out that a time-driven system with continuous state variables, usually modeled through (1)–(2), may be abstracted as a DES through some form of discretization in time and quantization in the state space. We should also point out that discrete *event* systems should not be confused with discrete *time* systems. The class of discrete time systems contains both time-driven and event-driven systems.
Models for Discrete Event Systems: An Overview, Fig. 1 Comparison of time-driven and event-driven state trajectories

Timed and Untimed Models of Discrete Event Systems

Returning to Fig. 1, instead of constructing the piecewise constant function $x(t)$ as shown, it is convenient to simply write the timed sequence of events $\{(e_1, t_1), (e_2, t_2), (e_3, t_3), (e_4, t_4), (e_5, t_5)\}$ which contains the same information as the state trajectory. Assuming that the initial state of the system (s_2 in this case) is known and that the system is "deterministic" in the sense that the next state after the occurrence of an event is unique, we can recover the state of the system at any point in time and reconstruct the DES state trajectory. The set of all possible timed sequences of events that a given system can ever

execute is called the *timed language* model of the system. The word "language" comes from the fact that we can think of the event E as an "alphabet" and of (finite) sequences of events as "words" (Hopcroft and Ullman 1979). We can further refine such a model by adding statistical information regarding the set of state trajectories (sample paths) of the system. Let us assume that probability distribution functions are available about the "lifetime" of each event type $e \in E$, that is, the elapsed time between successive occurrences of this particular e. A *stochastic timed language* is a timed language together with associated probability distribution functions for the events.

Stochastic timed language modeling is the most detailed in the sense that it contains event information in the form of event occurrences and their orderings, information about the exact times at which the events occur (not only their relative ordering), and statistical information about successive occurrences of events. If we delete the timing information from a timed language, we obtain an *untimed language*, or simply *language*, which is the set of all possible orderings of events that could happen in the given system. For example, the untimed sequence corresponding to the timed sequence of events in Fig. 1 is $\{e_1, e_2, e_3, e_4, e_5\}$.

Untimed and timed languages represent different levels of abstraction at which DES are modeled and studied. The choice of the appropriate level of abstraction clearly depends on the objectives of the analysis. In many instances, we are interested in the "logical behavior" of the system, that is, in ensuring that all the event sequences it can generate satisfy a given set of specifications, e.g., maintaining a precise ordering of events. In this context, the actual timing of events is not required, and it is sufficient to model only the untimed behavior of the system. *Supervisory control* that is discussed in the article ▸ Supervisory Control of Discrete-Event Systems is the term established for describing the systematic means (i.e., enabling or disabling events which are controllable) by which the logical behavior of a DES is regulated to achieve a given

specification (Cassandras and Lafortune 2008; Moody and Antsaklis 1998; Ramadge and Wonham 1987).

On the other hand, we may be interested in *event timing* in order to answer questions such as the following: "How much time does the system spend at a particular state?" or "Can this sequence of events be completed by a particular deadline?" More generally, event timing is important in assessing the performance of a DES often measured through quantities such as *throughput* or *response time*. In these instances, we need to consider the timed language model of the system. Since DES frequently operate in a stochastic setting, an additional level of complexity is introduced, necessitating the development of probabilistic models and related analytical methodologies for design and performance analysis based on stochastic timed language models. *Sample path analysis* and *perturbation analysis*, discussed in the entry ▸ Perturbation Analysis of Discrete Event Systems, refer to the study of sample paths of DES, focusing on the extraction of information for the purpose of efficiently estimating performance sensitivities of the system and, ultimately, achieving online control and optimization (Cassandras and Lafortune 2008; Glasserman 1991; Ho and Cao 1991; Ho and Cassandras 1983).

These different levels of abstraction are complementary, as they address different issues about the behavior of a DES. Although the language-based approach to DES modeling is attractive, it is by itself not convenient to address verification, controller synthesis, or performance issues. This motivates the development of *discrete event modeling formalisms* which represent languages in a manner that highlights structural information about the system behavior and can be used to address analysis and controller synthesis issues. Next, we provide an overview of three major modeling formalisms which are used by most (but not all) system and control theoretic methodologies pertaining to DES. Additional modeling formalisms encountered in the computer science literature include process algebras (Baeten and Weijland 1990) and communicating sequential processes (Hoare 1985).

M

Automata

A *deterministic automaton*, denoted by G, is a six-tuple

$$G = (\mathcal{X}, \mathcal{E}, f, \Gamma, x_0, \mathcal{X}_m),$$

where $\mathcal{X}$ is the set of *states*, $\mathcal{E}$ is the finite set of *events* associated with the transitions in G, and $f : \mathcal{X} \times \mathcal{E} \rightarrow \mathcal{X}$ is the *transition function*; specifically, $f(x, e) = y$ means that there is a transition labeled by event e from state x to state y and, in general, f is a *partial* function on its domain. $\Gamma : \mathcal{X} \rightarrow 2^{\mathcal{E}}$ is the *active event function* (or feasible event function); $\Gamma(x)$ is the set of all events e for which $f(x, e)$ is defined and it is called the *active event set* (or feasible event set) of G at x. Finally, x_0 is the *initial state* and $\mathcal{X}_m \subseteq \mathcal{X}$ is the set of *marked states*. The terms *state machine* and *generator* (which explains the notation G) are also used to describe the above object. Moreover, if $\mathcal{X}$ is a finite set, we call G a *deterministic finite-state automaton*. A *nondeterministic* automaton is defined by means of a relation over $\mathcal{X} \times \mathcal{E} \times \mathcal{X}$ or, equivalently, a function from $\mathcal{X} \times \mathcal{E}$ to $2^{\mathcal{X}}$.

The automaton G operates as follows. It starts in the initial state x_0, and upon the occurrence of an event $e \in \Gamma(x_0) \subseteq \mathcal{E}$, it makes a transition to state $f(x_0, e) \in \mathcal{X}$. This process then continues based on the transitions for which f is defined. Note that an event may occur without changing the state, i.e., $f(x, e) = x$. It is also possible that two distinct events occur at a given state causing the exact same transition, i.e., for $a, b \in \mathcal{E}$, $f(x, a) = f(x, b) = y$. What is interesting about the latter fact is that we may not be able to distinguish between events a and b by simply observing a transition from state x to state y.

For the sake of convenience, f is always extended from domain $\mathcal{X} \times \mathcal{E}$ to domain $\mathcal{X} \times \mathcal{E}^*$, where $\mathcal{E}^*$ is the set of *all* finite strings of elements of $\mathcal{E}$, including the empty string (denoted by ε); the $*$ operation is called the *Kleene closure*. This is accomplished in the following recursive manner: $f(x, \varepsilon) := x$ and $f(x, se) := f(f(x, s), e)$ for $s \in \mathcal{E}^*$ and $e \in \mathcal{E}$. The (untimed) language generated by G and denoted by $\mathcal{L}(G)$ is the set of all strings in $\mathcal{E}^*$ for which the extended function f is defined. The automaton model above is one instance of what is referred to as a *generalized semi-Markov scheme* (GSMS) in the literature of stochastic processes. A GSMS is viewed as the basis for extending automata to incorporate an event timing structure as well as nondeterministic state transition mechanisms, ultimately leading to *stochastic timed automata*, discussed in the sequel.

Let us allow for generally countable sets $\mathcal{X}$ and E and leave out of the definition any consideration for marked states. Thus, we begin with an automaton model $(\mathcal{X}, \mathcal{E}, f, \Gamma, x_0)$. We extend the modeling setting to *timed* automata by incorporating a "clock structure" associated with the event set E which now becomes the input from which a specific event sequence can be deduced. The *clock structure* (or *timing structure*) associated with an event set $\mathcal{E}$ is a set $\mathbf{V} = \{\mathbf{v}_i : i \in \mathcal{E}\}$ of clock (or lifetime) sequences

$$\mathbf{v}_i = \{v_{i,1}, v_{i,2}, \ldots\}, i \in \mathcal{E}, v_{i,k} \in \mathbb{R}^+, k = 1, 2, \ldots$$

Timed Automaton. A *timed automaton* is defined as a six-tuple

$$(\mathcal{X}, \mathcal{E}, f, \Gamma, x_0, \mathbf{V}),$$

where $\mathbf{V} = \{\mathbf{v}_i : i \in \mathcal{E}\}$ is a clock structure and $(\mathcal{X}, \mathcal{E}, f, \Gamma, x_0)$ is an automaton. The automaton generates a state sequence $x' = f(x, e')$ driven by an event sequence $\{e_1, e_2, \ldots\}$ generated through

$$e' = \arg \min_{i \in \Gamma(x)} \{y_i\} \tag{3}$$

with the clock values $y_i, i \in \mathcal{E}$, defined by

$$y_i' = \begin{cases} y_i - y^* & \text{if } i \neq e' \text{ and } i \in \Gamma(x) \\ v_{i, N_i + 1} & \text{if } i = e' \text{ or } i \notin \Gamma(x) \end{cases} \quad i \in \Gamma(x') \tag{4}$$

where the *interevent time* y^* is defined as

$$y^* = \min_{i \in \Gamma(x)} \{y_i\} \tag{5}$$

and the *event scores* N_i, $i \in \mathcal{E}$, are defined by

$$N_i' = \begin{cases} N_i + 1 \text{ if } i = e' \text{ or } i \notin \Gamma(x) \\ N_i \qquad \text{otherwise} \end{cases} \quad i \in \Gamma(x'). \tag{6}$$

In addition, initial conditions are $y_i = v_{i,1}$ and $N_i = 1$ for all $i \in \Gamma(x_0)$. If $i \notin \Gamma(x_0)$, then y_i is undefined and $N_i = 0$.

A simple interpretation of this elaborate definition is as follows. Given that the system is at some state x, the next event e' is the one with the smallest clock value among all feasible events $i \in \Gamma(x)$. The corresponding clock value, y^*, is the interevent time between the occurrence of e and e', and it provides the amount by which the time, t, moves forward: $t' = t + y^*$. Clock values for all events that remain active in state x' are decremented by y^*, except for the triggering event e' and all newly activated events, which are assigned a new lifetime v_{i,N_i+1}. Event scores are incremented whenever a new lifetime is assigned to them. It is important to note that the "system clock" t is fully controlled by the occurrence of events, which cause it to move forward; if no event occurs, the system remains at the last state observed.

Comparing $x' = f(x, e')$ to the state equation (1) for time-driven systems, we see that the former can be viewed as the event-driven analog of the latter. However, the simplicity of $x' = f(x, e')$ is deceptive: unless an event sequence is given, determining the *triggering* event e' which is required to obtain the next state x' involves the combination of (3)–(6). Therefore, the analog of (1) as a "canonical" state equation for a DES requires all Eqs. (3)–(6). Observe that this timed automaton generates a timed language, thus extending the untimed language generated by the original automaton G.

In the definition above, the clock structure **V** is assumed to be fully specified in a deterministic sense and so are state transitions dictated by $x' = f(x, e')$. The sequences $\{v_i\}$, $i \in \mathcal{E}$, can be extended to be specified only as stochastic sequences through distribution functions denoted by F_i, $i \in \mathcal{E}$. Thus, the *stochastic clock structure* (or *stochastic timing structure*) associated with

an event set $\mathcal{E}$ is a set of distribution functions $F = \{F_i : i \in \mathcal{E}\}$ characterizing the stochastic clock sequences

$$\{V_{i,k}\} = \{V_{i,1}, V_{i,2}, \ldots\}, \ i \in \mathcal{E},$$
$$V_{i,k} \in \mathbb{R}^+, \ k = 1, 2, \ldots$$

It is usually assumed that each clock sequence consists of random variables which are independent and identically distributed (iid) and that all clock sequences are mutually independent. Thus, each $\{V_{i,k}\}$ is completely characterized by a distribution function $F_i(t) = P[V_i \leq t]$. There are, however, several ways in which a clock structure can be extended to include situations where elements of a sequence $\{V_{i,k}\}$ are correlated or two clock sequences are interdependent. As for state transitions which may be nondeterministic in nature, such behavior is modeled through state transition probabilities as explained next.

Stochastic Timed Automaton. We can extend the definition of a timed automaton by viewing the state, event, and all event scores and clock values as random variables denoted respectively by capital letters X, E, N_i, and Y_i, $i \in \mathcal{E}$. Thus, a *stochastic timed automaton* is a six-tuple

$$(\mathcal{X}, \mathcal{E}, \Gamma, p, p_0, F),$$

where $\mathcal{X}$ is a countable *state space*; $\mathcal{E}$ is a countable *event set*; $\Gamma(x)$ is the *active event set* (or feasible event set); $p(x'; x, e')$ is a *state transition probability* defined for all $x, x' \in \mathcal{X}$, $e' \in \mathcal{E}$ and such that $p(x'; x, e') = 0$ for all $e' \notin \Gamma(x)$; p_0 is the probability mass function $P[X_0 = x]$, $x \in \mathcal{X}$, of the initial state X_0; and F is a *stochastic clock structure*. The automaton generates a stochastic state sequence $\{X_0, X_1, \ldots\}$ through a transition mechanism (based on observations $X = x$, $E' = e'$):

$$X' = x' \text{ with probability } p(x'; x, e') \quad (7)$$

and it is driven by a stochastic event sequence $\{E_1, E_2, \ldots\}$ generated exactly as in (3)–(6) with random variables E, Y_i, and N_i, $i \in \mathcal{E}$, instead

of deterministic quantities and with $\{V_{i,k}\} \sim F_i$ ($\sim$ denotes "with distribution"). In addition, initial conditions are $X_0 \sim p_0(x)$, $Y_i = V_{i,1}$, and $N_i = 1$ if $i \in \Gamma(X_0)$. If $i \notin \Gamma(X_0)$, then Y_i is undefined and $N_i = 0$.

It is conceivable for two events to occur at the same time, in which case we need a priority scheme to overcome a possible ambiguity in the selection of the triggering event in (3). In practice, it is common to expect that every F_i in the clock structure is absolutely continuous over $[0, \infty)$ (so that its density function exists) and has a finite mean. This implies that two events can occur at exactly the same time only with probability 0.

A stochastic process $\{X(t)\}$ with state space $\mathcal{X}$ which is generated by a stochastic timed automaton $(\mathcal{X}, \mathcal{E}, \Gamma, p, p_0, F)$ is referred to as a *generalized semi-Markov process* (GSMP). This process is used as the basis of much of the sample path analysis methods for DES (see Cassandras and Lafortune 2008; Glasserman 1991; Ho and Cao 1991).

Petri Nets

An alternative modeling formalism for DES is provided by *Petri nets*, originating in the work of C. A. Petri in the early 1960s. Like an automaton, a Petri net (Peterson 1981) is a device that manipulates events according to certain rules. One of its features is the inclusion of explicit conditions under which an event can be enabled. The Petri net modeling framework is the subject of the article ▶ Modeling, Analysis, and Control with Petri Nets. Thus, we limit ourselves here to a brief introduction. First, we define a Petri net graph, also called the *Petri net structure*. Then, we adjoin to this graph an initial state, a set of marked states, and a transition labeling function, resulting in the complete Petri net model, its associated dynamics, and the languages that it generates and marks.

Petri Net Graph. A Petri net is a directed *bipartite graph* with two types of nodes, *places* and *transitions*, and arcs connecting them. Events

are associated with transition nodes. In order for a transition to occur, several conditions may have to be satisfied. Information related to these conditions is contained in place nodes. Some such places are viewed as the "input" to a transition; they are associated with the conditions required for this transition to occur. Other places are viewed as the output of a transition; they are associated with conditions that are affected by the occurrence of this transition. A *Petri net graph* is formally defined as a weighted directed bipartite graph (P, T, A, w) where P is the finite set of *places* (one type of node in the graph), T is the finite set of *transitions* (the other type of node in the graph), $A \subseteq (P \times T) \cup (T \times P)$ is the set of arcs with directions from places to transitions and from transitions to places in the graph, and $w : A \rightarrow \{1, 2, 3, \ldots\}$ is the *weight function* on the arcs. Let $P = \{p_1, p_2, \ldots, p_n\}$, and $T = \{t_1, t_2, \ldots, t_m\}$. It is convenient to use $I(t_j)$ to represent the set of input places to transition t_j. Similarly, $O(t_j)$ represents the set of output places from transition t_j. Thus, we have $I(t_j) = \{p_i \in P : (p_i, t_j) \in A\}$ and $O(t_j) = \{p_i \in P : (t_j, p_i) \in A\}$.

Petri Net Dynamics. *Tokens* are assigned to places in a Petri net graph in order to indicate the fact that the condition described by that place is satisfied. The way in which tokens are assigned to a Petri net graph defines a *marking*. Formally, a *marking* x of a Petri net graph (P, T, A, w) is a function $x : P \rightarrow \mathbb{N} = \{0, 1, 2, \ldots\}$. Marking x defines row vector $\mathbf{x} = [x(p_1), x(p_2), \ldots, x(p_n)]$, where n is the number of places in the Petri net. The ith entry of this vector indicates the (nonnegative integer) number of tokens in place p_i, $x(p_i) \in \mathbb{N}$. In Petri net graphs, a token is indicated by a dark dot positioned in the appropriate place. The *state* of a Petri net is defined to be its marking vector $\mathbf{x}$. The state transition mechanism of a Petri net is captured by the structure of its graph and by "moving" tokens from one place to another. A transition $t_j \in T$ in a Petri net is said to be *enabled* if

$$x(p_i) \geq w(p_i, t_j) \text{ for all } p_i \in I(t_j) . \quad (8)$$

In words, transition t_j in the Petri net is enabled when the number of tokens in p_i is at least as large as the weight of the arc connecting p_i to t_j, for all places p_i that are input to transition t_j. When a transition is enabled, it can occur or *fire*. The *state transition function* of a Petri net is defined through the change in the state of the Petri net due to the firing of an enabled transition. The state transition function, $f : \mathbb{N}^n \times T \to \mathbb{N}^n$, of Petri net (P, T, A, w, x) is defined for transition $t_j \in T$ if and only if (8) holds. Then, we set $\mathbf{x}' = f(\mathbf{x}, t_j)$ where

$$x'(p_i) = x(p_i) - w(p_i, t_j) + w(t_j, p_i),$$
$$i = 1, \ldots, n . \tag{9}$$

An "enabled transition" is therefore equivalent to a "feasible event" in an automaton. But whereas in automata the state transition function enumerates all feasible state transitions, here the state transition function is based on the structure of the Petri net. Thus, the next state defined by (9) explicitly depends on the input and output places of a transition and on the weights of the arcs connecting these places to the transition. According to (9), if p_i is an input place of t_j, it loses as many tokens as the weight of the arc from p_i to t_j; if it is an output place of t_j, it gains as many tokens as the weight of the arc from t_j to p_i. Clearly, it is possible that p_i is both an input and output place of t_j.

In general, it is entirely possible that, after several transition firings, the resulting state is $\mathbf{x} = [0, \ldots, 0]$ or that the number of tokens in one or more places grows arbitrarily large after an arbitrarily large number of transition firings. The latter phenomenon is a key difference with automata, where finite-state automata have only a finite number of states, by definition. In contrast, a finite Petri net graph may result in a Petri net with an unbounded number of states. It should be noted that a finite-state automaton can always be represented as a Petri net; on the other hand, not all Petri nets can be represented as finite-state automata.

Similar to timed automata, we can define *timed Petri nets* by introducing a clock structure, except that now a clock sequence $\mathbf{v}_j$ is associated with a transition t_j. A positive real number, $v_{j,k}$, assigned to t_j has the following meaning: when transition t_j is enabled for the kth time, it does not fire immediately, but incurs a firing delay given by $v_{j,k}$; during this delay, tokens are kept in the input places of t_j. Not all transitions are required to have firing delays. Thus, we partition T into subsets T_0 and T_D, such that $T = T_0 \cup T_D$. T_0 is the set of transitions always incurring zero firing delay, and T_D is the set of transitions that generally incur some firing delay. The latter are called *timed transitions*. The *clock structure* (or *timing structure*) associated with a set of timed transitions $T_D \subseteq T$ of a marked Petri net (P, T, A, w, x) is a set $\mathbf{V} = \{\mathbf{v}_j : t_j \in T_D\}$ of clock (or lifetime) sequences $\mathbf{v}_j = \{v_{j,1}, v_{j,2}, \ldots\}$, $t_j \in T_D$, $v_{j,k} \in \mathbb{R}^+$, $k = 1, 2, \ldots$ A *timed Petri net* is a six-tuple $(P, T, A, w, x, \mathbf{V})$, where (P, T, A, w, x) is a marked Petri net and $\mathbf{V} = \{\mathbf{v}_j : t_j \in T_D\}$ is a clock structure. It is worth mentioning that this general structure allows for a variety of behaviors in a timed Petri net, including the possibility of multiple transitions being enabled at the same time or an enabled transition being preempted by the firing of another, depending on the values of the associated firing delays. The need to analyze and control such behavior in DES has motivated the development of a considerable body of analysis techniques for Petri net models which have been proven to be particularly suitable for this purpose (Moody and Antsaklis 1998; Peterson 1981).

Dioid Algebras

Another modeling framework is based on developing an algebra using two operations: $\min\{a, b\}$ (or $\max\{a, b\}$) for any real numbers a and b and addition $(a + b)$. The motivation comes from the observation that the operations "min" and "+" are the only ones required to develop the timed automaton model. Similarly, the operations "max" and "+" are the only ones used in developing the timed Petri net models described above. The operations are formally named *addition* and *multiplication* and denoted by $\oplus$ and $\otimes$

respectively. However, their actual meaning (in terms of regular algebra) is different. For any two real numbers a and b, we define

Addition : $\quad a \oplus b \equiv \max\{a, b\}$ (10)

Multiplication : $\quad a \otimes b \equiv a + b.$ (11)

This dioid algebra is also called a $(\max, +)$ algebra (Baccelli et al. 1992; Cuninghame-Green 1979). If we consider a standard linear discrete time system, its state equation is of the form

$$\mathbf{x}(k + 1) = \mathbf{A}\mathbf{x}(k) + \mathbf{B}\mathbf{u}(k),$$

which involves (regular) multiplication $(\times)$ and addition $(+)$. It turns out that we can use a $(\max, +)$ algebra with DES, replacing the $(+, \times)$ algebra of conventional time-driven systems, and come up with a representation similar to the one above, thus paralleling to a considerable extent the analysis of classical time-driven linear systems. We should emphasize, however, that this particular representation is only possible for a subset of DES. Moreover, while conceptually this offers an attractive way to capture the event timing dynamics in a DES, from a computational standpoint, one still has to confront the complexity of performing the "max" operation when numerical information is ultimately needed to analyze the system or to design controllers for its proper operation.

Control and Optimization of Discrete Event Systems

The various control and optimization methodologies developed to date for DES depend on the modeling level appropriate for the problem of interest.

Logical Behavior. Issues such as ordering events according to some specification or ensuring the reachability of a particular state are normally addressed through the use of automata and Petri nets (Chen and Lafortune 1991; Moody and Antsaklis 1998; Ramadge and Wonham 1987). Supervisory control theory provides a systematic framework for formulating and solving problems of this type; a comprehensive coverage can be found in Cassandras and Lafortune (2008). Logical behavior issues are also encountered in the *diagnosis* of partially observed DES, a topic covered in the article ▶ Diagnosis of Discrete Event Systems.

Event Timing. When timing issues are introduced, timed automata and timed Petri nets are invoked for modeling purposes. Supervisory control in this case becomes significantly more complicated. An important class of problems, however, does not involve the ordering of individual events, but rather the requirement that selected events occur within a given "time window" or with some desired periodic characteristics. Models based on the algebraic structure of timed Petri nets or the $(\max, +)$ algebra provide convenient settings for formulating and solving such problems (Baccelli et al. 1992; Glasserman and Yao 1994).

Performance Analysis. As in classical control theory, one can define a performance (or cost) function as a means for quantifying system behavior. This approach is particularly crucial in the study of stochastic DES. Because of the complexity of DES dynamics, analytical expressions for such performance metrics in terms of controllable variables are seldom available. This has motivated the use of simulation and, more generally, the study of DES sample paths; these have proven to contain a surprising wealth of information for control purposes. The theory of *perturbation analysis* presented in the article ▶ Perturbation Analysis of Discrete Event Systems has provided a systematic way of estimating performance sensitivities with respect to system parameters (Cassandras and Lafortune 2008; Cassandras and Panayiotou 1999; Glasserman 1991; Ho and Cao 1991).

Discrete Event Simulation. Because of the aforementioned complexity of DES dynamics, simulation becomes an essential part of DES performance analysis (Law and Kelton 1991). Discrete event simulation can be defined as a

systematic way of generating sample paths of a DES by means of a timed automaton or its stochastic counterpart. The same process can be carried out using a Petri net model or one based on the dioid algebra setting.

Optimization. Optimization problems can be formulated in the context of both untimed and timed models of DES. Moreover, such problems can be formulated in both a deterministic and a stochastic setting. In the latter case, the ability to efficiently estimate performance sensitivities with respect to controllable system parameters provides a powerful tool for stochastic gradient-based optimization (when one can define derivatives) (Vázquez-Abad et al. 1998).

A treatment of all such problems from an application-oriented standpoint, along with further details on the use of the modeling frameworks discussed in this entry, can be found in the article ▶ Applications of Discrete-Event Systems.

Monotone Systems in Biology

David Angeli
Department of Electrical and Electronic Engineering, Imperial College London, London, UK
Dipartimento di Ingegneria dell'Informazione, University of Florence, Italy

Abstract

Mathematical models arising in biology might sometime exhibit the remarkable feature of preserving ordering of their solutions with

respect to initial data: in words, the "more" of x (the state variable) at time 0, the more of it at all subsequent times. Similar monotonicity properties are possibly exhibited also with respect to input levels. When this is the case, important features of the system's dynamics can be inferred on the basis of purely qualitative or relatively basic quantitative knowledge of the system's characteristics. We will discuss how monotonicity-related tools can be used to analyze and design biological systems with prescribed dynamical behaviors such as global stability, multistability, or periodic oscillations.

Keywords

Feedback interconnections; Monotone dynamics; Monotonicity checks

Introduction

Ordinary differential equations of a scalar unknown, under suitable assumptions for unicity of solutions, trivially enjoy the property that any pair of ordered initial conditions (according to the standard $\leq$ order defined for real numbers) gives rise to ordered solutions at all positive times (as well as negative, though this is less relevant for the developments that follow). Monotone systems are a special but significant class of dynamical models, possibly evolving in high-dimensional or even infinite-dimensional state spaces, that are nevertheless characterized by a similar property holding with respect to a suitably defined notion of partial order. They became the focus of considerable interest in mathematics after a series of seminal papers by Hirsch (1985, 1988) provided the basic definitions as well as deep results showing how generic convergence properties of their solutions are expected under suitable technical assumptions. Shortly before that Smale (1976), Smale's construction had already highlighted how specific solutions could instead exhibit

arbitrary behavior (including periodic or chaotic). Further results along these lines provide insight into which set of extra assumptions allow one to strengthen generic convergence to global convergence, including, for instance, existence of positive first integrals (Banaji and Angeli 2010; Mierczynski 1987), tridiagonal structure (Smillie 1984), or positive translation invariance (Angeli and Sontag 2008a).

While these tools were initially developed having in mind applications arising in ecology, epidemiology, chemistry, or economy, it was due to the increased importance of mathematical modeling in molecular biology and the subsequent rapid development of systems biology as an emerging independent field of investigation that they became particularly relevant to biology. The paper Angeli and Sontag (2003) first introduced the notion of control monotone systems, including input and output variables, that is of interest if one is looking at systems arising from interconnection of monotone modules. Small-gain theorems and related conditions were defined to study both positive (Angeli and Sontag 2004b) and negative (Angeli and Sontag 2003) feedback interconnections by relating their asymptotic behavior to properties of the discrete iterations of a suitable map, called the steady-state characteristic of the system.

In particular, convergence of this map is related to convergent solutions for the original continuous time system; on the other hand, specific negative feedback interconnections can instead give rise to oscillations as a result of Hopf bifurcations as in Angeli and Sontag (2008b) or to relaxation oscillators as highlighted in Gedeon and Sontag (2007).

A parallel line of investigation, originated in the work of Volpert et al. (1994), exploited the specific features of models arising in biochemistry by focusing on structural conditions for monotonicity of chemical reaction networks (Angeli et al. 2010; Banaji 2009). Monotonicity is only one of the possible tools adopted in the study of dynamics for such class of models in the related field of chemical reaction networks theory.

Mathematical Preliminaries

To illustrate the main tools of monotone dynamics, we consider the following systems defined on partially ordered input, state, and output spaces. Namely, along with the sets U, X, Y (which denote input, state, and output space, respectively), we consider corresponding partial orders $\succeq_X, \succeq_U, \succeq_Y$. A typical way of defining a partial order on a set S embedded in some Euclidean space E, $S \subset E$, is to first identify a cone K of positive vectors which belong to E. A cone in this context is any closed convex set which is preserved under multiplication times nonnegative scalars and such that $K \cap -K = \{0\}$. Accordingly we may denote $s_1 \succeq_S s_2$ whenever $s_1 - s_2 \in K$. A typical choice of K in the case of finite-dimensional $E = \mathbb{R}^n$ is the positive orthant, $(K = [0, +\infty)^n)$, in which case $\succeq$ can be interpreted as componentwise inequalities. More general orthants are also very useful in several applications as well as more exotic cones, smooth or polyhedral, according to the specific model considered. When dealing with input signals, we let $\mathcal{U}$ denote the set of locally essentially bounded and measurable functions of time. In particular, we inherit a partial order on $\mathcal{U}$ from the partial order on U according to the following definition:

$$u_1(\cdot) \succeq_\mathcal{U} u_2(\cdot) \ \Leftrightarrow \ u_1(t) \succeq_U u_2(t) \qquad \forall t \in \mathbb{R}.$$

When obvious from the context, we do not emphasize the space to which variables belong and simply write $\succeq$. Strict order notions are also of interest and especially relevant for some of the deepest implications of the theory. We let $s_1 \succ s_2$ denote $s_1 \succeq s_2$ and $s_1 \neq s_2$. While for partial orders induced by positivity cones, we let $s_1 \gg s_2$ denote $s_1 - s_2 \in \mathrm{int}(K)$.

A dynamical system is for us a continuous map $\varphi : \mathbb{R} \times X \to X$ which fulfills the property, $\varphi(0, x) = x$ for all $x \in X$ and $\varphi(t_2, \varphi(t_1, x)) = \varphi(t_1 + t_2, x)$ for all $t_1, t_2 \in \mathbb{R}$. Sometimes, when solutions are not globally defined (for instance, if the system is defined through a set of nonlinear differential equations), it is enough to restrict the definitions that follow to the domain of existence of solutions.

Definition 1 A monotone system φ is one that fulfills the following:

$$\forall x_1, x_2 \in X : x_1 \succeq x_2 \qquad \varphi(t, x_1) \succeq \varphi(t, x_2)$$
$$\forall t \geq 0. \qquad (1)$$

A system φ is strongly monotone when the following holds:

$$\forall x_1, x_2 \in X : x_1 \succ x_2 \qquad \varphi(t, x_1) \gg \varphi(t, x_2)$$
$$\forall t > 0. \qquad (2)$$

A control system is characterized by two continuous mappings: $\varphi : \mathbb{R} \times X \times \mathcal{U} \to X$ and the readout map $h : X \times U \to Y$.

Definition 2 A control system is monotone if

$$\forall u_1, u_2 \in \mathcal{U} : u_1 \succeq u_2, \quad \forall x_1, x_2 \in X : x_1 \succeq x_2,$$
$$\forall t \geq 0 \quad \varphi(t, x_1, u_1) \succeq \varphi(t, x_2, u_2) \quad (3)$$

and

$$\forall u_1, u_2 \in U : u_1 \succeq u_2, \quad \forall x_1, x_2 \in X : x_1 \succeq x_2,$$
$$h(x_1, u_1) \succeq h(x_2, u_2). \quad (4)$$

Notice that for any ordered state and input pairs x_1, x_2, u_1, u_2, the signals y_1 and y_2 defined as $y_1(t) := h(\varphi(t, x_1, u_1), u_1(t))$, $y_2(t) := h(\varphi(t, x_2, u_2), u_2(t))$ also fulfill, thanks to the Definition 2, $y_1(t) \succeq_Y y_2(t)$ (for all $t \geq 0$).

A system which is monotone with respect to the positive orthant is called cooperative. If a system is cooperative after reverting the direction of time, it is called competitive. Checking if a mathematical model specified by differential equations is monotone with respect to the partial order induced by some cone K is not too difficult. In particular, monotonicity, in its most basic formulation (1), simply amounts to a check of positive invariance of the set $\Gamma := \{(x_1, x_2) \in X^2 : x_1 \succeq x_2\}$ for a system formed by two copies of φ in parallel. This can be assessed without explicit knowledge of solutions, for instance, by using the notion of tangent cones and Nagumo's theorem (Angeli and Sontag 2003). Sufficient

conditions also exist to assess strong monotonicity, for instance, in the case of orthant cones. Finding whether there exists an order (as induced, for instance, by a suitable cone K) which can make a system monotone is instead a harder task which normally entails a good deal of insight in the systems dynamics.

It is worth mentioning that for the special case of linear systems, monotonicity is just equivalent to invariance of the cone K, as incremental properties (referred to pairs of solutions) are just equivalent to their non-incremental counterparts (referred to the 0 solution). In this respect, a substantial amount of theory exists starting from classical works such as the Perron-Frobenius theory on positive and cone-preserving maps; this is, however, outside the scope of this entry, and the interested reader may refer to Farina and Rinaldi (2000) for a recent book on the subject.

Monotone Dynamics

We divide this section in three parts; first we summarize the main tools for checking monotonicity with respect to orthant cones, then we recall some of the main consequences of monotonicity for the long-term behavior of solutions and, finally, we study interconnections of monotone systems.

Checking Monotonicity

Orthant cones and the partial orders they induce play a major role in biology applications. In fact, for systems described by equations

$$\dot{x} = f(x) \tag{5}$$

with $X \subset \mathbb{R}^n$ open and $f : X \to \mathbb{R}^n$ of class $\mathcal{C}^1$, the following characterization holds:

Proposition 1 *The system φ induced by the set of differential equations (5) is cooperative if and only if the Jacobian $\frac{\partial f}{\partial x}$ is a Metzler matrix for all $x \in X$.*

We recall that M is Metzler if $m_{ij} \geq 0$ for all $i \neq j$. Let $\Lambda = \text{diag}[\lambda_1, \ldots, \lambda_n]$ with $\lambda_i \in \{-1, 1\}$ and assume that the orthant $\mathcal{O} = \Lambda[0, +\infty)^n$. It is straightforward to see that $x_1 \succeq_{\mathcal{O}} x_2 \quad \Leftrightarrow$

$\Lambda x_1 \succeq \Lambda x_2$, where $\succeq$ denotes the partial order induced by the positive orthant, while $\succeq_{\mathcal{O}}$ denotes the order induced by $\mathcal{O}$. This means that we may check monotonicity with respect to $\mathcal{O}$ by performing a simple change of coordinates $z = \Lambda x$. As a corollary:

Proposition 2 *The system φ induced by the set of differential equations (5) is monotone with respect to $\succeq_{\mathcal{O}}$ if and only if $\Lambda \frac{\partial f}{\partial x} \Lambda$ is a Metzler matrix for all $x \in X$.*

Notice that conditions of Propositions 1 and 2 can be expressed in terms of sign constraints on off-diagonal entries of the Jacobian; in biological terms a sign constraint in an off-diagonal entry amounts to asking that a particular species (meaning chemical compound or otherwise) consistently exhibit throughout the considered model's state space either an excitatory or inhibitory effect on some other species of interest. Qualitative diagrams showing effects of species on each other are commonly used by biologists to understand the working principles of biomolecular networks.

Remarkably, Proposition 2 has also an interesting graph theoretical interpretation if one thinks of sign $\left(\frac{\partial f}{\partial x}\right)$ as the adjacency matrix of a graph with nodes $x_1 \ldots x_n$ corresponding to the state variables of the system.

Proposition 3 *The system φ induced by the set of differential equations (5) is monotone with respect to $\succeq_{\mathcal{O}}$ if and only if the directed graph of adjacency matrix sign $\left(\frac{\partial f}{\partial x}\right)$ (neglecting diagonal entries) has undirected loops with an even number of negative edges.*

This means in particular that $\frac{\partial f}{\partial x}$ must be sign symmetric (no predator-prey-type interactions) and in addition that a similar parity property has to hold on undirected loops of arbitrary length. Sufficient conditions for strong monotonicity are also known, for instance, in terms of irreducibility of the Jacobian matrix (Kamke's condition; see Hirsch and Smith 2003).

Asymptotic Dynamics
As previously mentioned, several important implications of monotonicity are with respect to

asymptotic dynamics. Let $\mathcal{E}$ denote the set of equilibria of φ. The following result is due to Hirsch (1985).

Theorem 1 *Let φ be a strongly monotone system with bounded solutions. There exists a zero measure set Q such that each solution starting in $X \setminus Q$ converges toward $\mathcal{E}$.*

Global convergence results can be achieved for important classes of monotone dynamics. For instance, when increasing conservation laws are present (see Banaji and Angeli 2010):

Theorem 2 *Let $X \subset K \subset \mathbb{R}^n$ be any two proper cones. Let φ on X be strongly monotone with respect to the partial order induced by K and preserving a K-increasing first integral. Then every bounded solution converges.*

Dually to first integrals, positive translation invariance of the dynamics also provide grounds for global convergence (see Angeli and Sontag 2008a):

Theorem 3 *If a system is strongly monotone and fulfills $\varphi(t, x_0 + hv) = \varphi(t, x_0) + hv$ for all $h \in \mathbb{R}$ and some $v \gg 0$, then all solutions with bounded projections in $v^{\perp}$ converge.*

The class of tridiagonal cooperative systems has also been investigated as a significant remarkable class of global convergent dynamics; see Smillie (1984). These arise from differential equations $\dot{x} = f(x)$ when $\partial f_i / \partial x_j = 0$ for all $|i - j| > 1$. Finally it is worth emphasizing how significant for biological systems, often subject to phenomena evolving at different timescales, are also results on singular perturbations (Gedeon and Sontag 2007; Wang and Sontag 2008).

Interconnected Monotone Systems
Results on interconnected monotone SISO systems are surveyed in Angeli and Sontag (2004a). The main tool used in this context is the notion of input-state and input–output steady-state characteristic.

Definition 3 A control system admits a well-defined input-state characteristic if for all constant inputs u there exists a unique globally asymptotically stable equilibrium $k_x(u)$ and the map $k_x(u)$ is continuous. If moreover the equilibrium is hyperbolic, then k_x is called a non-degenerate characteristic. The input–output characteristic is defined as $k_y(u) = h(k_x(u))$.

Let φ be system with a well-defined input–output characteristic k_y; we may define the iteration

$$u_{k+1} = k_y(u_k). \qquad (6)$$

It is clear that fixed points of (6) correspond to input values (and therefore to equilibria through the characteristic map k_x) of the closed-loop system derived by considering the unity feedback interconnection $u = y$. What is remarkable for monotone systems is that both in the case of positive and negative feedback and in a precise sense, stability properties of the fixed points of the discrete iteration (6) are matched by stability properties of the corresponding associated solutions of the original continuous time system. See Angeli and Sontag (2004b) for the case of positive feedback interconnections and Angeli et al. (2004) for applications of such results to synthesis and detection of multistability in molecular biology.

Multistability, in particular, is an important dynamical feature of specific cellular systems and can be achieved, with good degree of robustness with respect to different types of uncertainties, by means of positive feedback interconnections of monotone subsystems. The typical input–output characteristic k_y giving rise to such behavior is, in the SISO case, that of a sigmoidal function intersecting in 3 points the diagonal $u = y$. Two of the fixed points, namely, u_1 and u_3 (see Fig. 1), are asymptotically stable for (6), and the corresponding equilibria of the original continuous time monotone system are also asymptotically stable with a basin of attraction which covers almost all initial conditions. The fixed-point u_2 is unstable and the corresponding equilibrium is also such (under suitable technical assumption on the non-degeneracy of the I-O characteristic). Extensions of similar criteria to the MIMO case are presented in Enciso and Sontag (2005).
Monotone Systems in Biology, Fig. 1 Fixed points of a sigmoidal input–output characteristic

Monotone Systems in Biology, Fig. 2 Fixed point of a decreasing input–output characteristic

Negative feedback normally destroys monotonicity. As a result, the likelihood of complex dynamical behavior is highly increased. Nevertheless, input–output characteristics still can provide useful insight in the system's dynamics at least in the case of low feedback gain or, for high feedback gains, in the presence of sufficiently large delays. For instance, unity negative feedback interconnection of a SISO monotone system may give rise to a unique and globally asymptotically stable fixed point of (6), thanks to the decreasingness of the input–output characteristic and as shown in Fig. 2. Under such circumstances a small-gain result applies and global asymptotic stability of the corresponding equilibrium is guaranteed regardless of arbitrary input delays in the systems. See Angeli and Sontag (2003) for the simplest small-gain theorem developed in the context of SISO negative feedback interconnections of monotone systems and Enciso and Sontag (2006) for generalizations to systems with multiple inputs as well as delays. A generalization of small-gain results to the case of MIMO systems which are neither in a positive nor negative feedback configuration is presented in Angeli and Sontag (2011).

When the iteration (6) has an unstable fixed point, for instance, it converges to a period-2 solution, one may expect insurgence of oscillations around the equilibrium through a Hopf bifurcation provided sufficiently large delays in the input channels are allowed. This situation is analyzed in Angeli and Sontag (2008b) and illustrated through the study of the classical Golbeter's model for the *Drosophila*'s circadian rhythm.

Summary and Future Directions

Verifying that a control system preserves some ordering of initial conditions provides important and far-reaching implications for its dynamics. Insurgence of specific behaviors can often be inferred on the basis of purely qualitative knowledge (as in the case of Hirsch's generic convergence theorem) as well as additional basic quantitative knowledge as in the case of positive and negative feedback interconnections of monotone systems. For the above reasons, applications in molecular biology of monotone system's theory are gradually emerging: for instance, in the study of MAPK cascades or circadian oscilla-

tions, as well as in Chemical Reaction Networks Theory. Generally speaking, while monotonicity as a whole cannot be expected in large networks, experimental data shows that the number of negative feedback loops in biological regulatory networks is significantly lower than in a random signed graph of comparable size Maayan et al. (2008).

Analyzing the properties of monotone dynamics may potentially lead to better understanding of the key regulatory mechanisms of complex networks as well as the development of bottom-up approaches for the identification of meaningful submodules in biological networks. Potential research directions may include both novel computational tools and specific applications to systems biology, for instance:

- Algorithms for detection of monotonicity with respect to exotic orders (such as arbitrary polytopic cones or even state-dependent cones)
- Application of monotonicity-based ideas to control synthesis (see, for instance, Aswani and Tomlin (2009) where the special class of piecewise affine systems is considered)

Motion Description Languages and Symbolic Control

Sean B. Andersson
Mechanical Engineering and Division of
Systems Engineering, Boston University,
Boston, MA, USA

Abstract

The fundamental idea behind symbolic control is to mitigate the complexity of a dynamic system by limiting the set of available controls to a typically finite collection of symbols. Each symbol represents a control law that may be either open or closed loop. With these symbols, a simpler description of the motion of the system can be created, thereby easing the challenges of analysis and control design. In this entry, we provide a high-level description of symbolic control; discuss briefly its history, connections, and applications; and provide a few insights into where the field is going.

Keywords

Abstraction; Complex systems; Formal methods

Introduction

Systems and control theory is powerful paradigm for analyzing, understanding, and controlling dynamic systems. Traditional tools in the field for developing and analyzing control laws, however, face significant challenges when one needs to deal with the complexity that arises in many practical, real-world settings such as the control of autonomous, mobile systems operating in uncertain and changing physical environments. This is particularly true when the tasks to be achieved are not easily framed in terms of motion to a point in the state space. One of the primary goals of symbolic control is to mitigate this complexity by abstracting some combination of the system dynamics, the space of control inputs, and the physical environment to a simpler, typically finite, model.

This fundamental idea, namely, that of abstracting away the complexity of the underlying dynamics and environment, is in fact a quite natural one. Consider, for example, how you give instructions to another person wanting to go to a point of interest. It would be absurd to provide details at the level of their actuators, namely, with commands to their individual muscles (or to carry the example to an even more absurd extreme, to the dynamic components that make up those muscles). Rather, very high-level commands are given, such as "follow the road," "turn right," and so on. Each of these provides a description of what to do with the understanding that the person can carry out those commands in their own fashion. Similarly, the environment itself is abstracted, and only elements meaningful to the task at hand are described. Thus, continuing the example above, rather than

providing metric information or a detailed map, the instructions may use environmental features to determine when particular actions should be terminated and the next begun, such as "follow the road until the second intersection, then turn right."

Underlying the idea of symbolic control is the notion that rich behaviors can result from simple actions. This premise was used in many early robots and can be traced back at least to the ideas of Norbert Wiener on cybernetics (see Arkin 1998). It is at the heart of the behavior-based approach to robotics (Brooks 1986). Similar ideas can also be seen in the development of a high-level language (G-codes) for Computer Numerically Controlled (CNC) machines. The key technical ideas in the more general setting of symbolic control for dynamic systems can be traced back to Brockett (1988) which introduced ideas of formalizing a modular approach to programming motion control devices through the development of a Motion Description Language (MDL).

The goal of the present work is to introduce the interested reader to the general ideas of symbolic control as well as to some of its application areas and research directions. While it is not a survey paper, a few select references are provided throughout to point the reader in hopefully fruitful directions into the literature.

Models and Approaches

There are at least two related but distinct approaches to symbolic control. Both begin with a mathematical description of the system, typically given as an ordinary differential equation of the form

$$\dot{x} = f(x, u, t), \qquad y = h(x, t) \qquad (1)$$

where x is a vector describing the state of the system, y is the output of the sensors of the system, and u is the control input.

Under the first approach to symbolic control, the focus is on reducing the complexity of the space of possible control signals by limiting the system to a typically finite collection of control symbols. Each of these symbols represents a control law that may be open loop or may utilize output feedback. For example, *follow the road* could be a feedback control law that uses sensor measurements to determine the position relative to the road and then applies steering commands so that the system stays on the road while simultaneously maintaining a constant speed. There are, of course, many ways to accomplish the specifics of this task, and the details will depend on the particular system. Thus, an autonomous four-wheeled vehicle equipped with a laser range finder, an autonomous motorcycle equipped with ultrasonic sensors, or an autonomous aerial vehicle with a camera would each carry out the command in their own way, and each would have very different trajectories. They would all, however, satisfy the notion of *follow the road*. Description of the behavior of the system can then be given in terms of the abstract symbols rather than in terms of the details of the trajectories.

Typically each of these symbols describes an action that at least conceptually is simple. In order to generate rich motions to carry out complex tasks, the system is switched between the available symbols. Switching conditions are often referred to as *interrupts*. Interrupts may be purely time-based (e.g., apply a given symbol for T seconds) or may be expressed in terms of symbols representing certain environmental conditions. These may be simple function of the measurements (e.g., interrupt when an intersection is detected) or may represent more complicated scenarios with history and dynamics (e.g., interrupt after the second intersection is detected). Just as the input symbols abstract away the details of the control space and of the motion of the system, the interrupt symbols abstract away the details of the environment. For example, *intersection* has a clear high-level meaning but a very different sensor "signature" for particular systems.

As a simple illustrative example, consider a collection of control symbols designed for moving along a system of roads, {*follow road*, *turn right*, *turn left*}, and a collection of interrupt
Motion Description Languages and Symbolic Control, Fig. 1 Simple example of symbolic control with a focus on abstracting the inputs. Two systems, a snakelike robot and an autonomous car, are given a high-level plan in terms of symbols for navigating a right-hand turn. The systems each interpret the same symbols in their own ways, leading to different trajectories due both to differences in dynamics and also to different sensors cues as caused, for example, by the parked vehicle encountered by the car in this scenario

symbols for triggering changes in such a setting, {*in intersection*, *clear of intersection*}. Suppose there are two vehicles that can each interpret these symbols, an autonomous car and a snake-like robot, as illustrated in Fig. 1. It is reasonable to assume that the control symbols each describe relatively complex dynamics that allow, for example, for obstacle avoidance while carrying out the action. Figure 1 illustrates a possible situation where the two systems carry out the plan defined by the symbolic sequence:

(*Follow the road* UNTIL *in intersection*)
(*Turn right* UNTIL *clear of intersection*)

The intent of this plan is for the system to navigate a right-hand turn. As shown in the figure, the actual trajectories followed by the systems can be markedly different due in part to system dynamics (the snakelike robot undulates, while the car does not) as well as to different sensor responses (when the car goes through, there is a parked vehicle that it must navigate around, while the snakelike robot found a clear path during its execution). Despite these differences, both systems achieve the goal of the plan.

The collection of control and interrupt symbols can be thought of as a language for describing and specifying motion and are used to write programs that can be compiled into an executable for a specific system. Different rules for doing this can be established that define different languages, analogous to different high-level programming languages such as C++, Java, or Python. Further details can be found in, for example, Manikonda et al. (1998).

Under the second approach, the focus is on representing the dynamics and state space (or environment) of the system in an abstract, symbolic way. The fundamental idea is to lump all the states in a region into a single abstract element and to then represent the entire system with a finite number of these elements. Control laws are then defined that steer all the states in one element into some state in a different region. The symbolic control system is then the finite set of elements representing regions together with the finite set of controllers for moving between them. It can be thought of essentially as a graph (or more accurately as a transition system) in which the nodes represent regions in the state space and the edges represent achievable transitions between them. The goal of this abstraction step is for the two representations to be equivalent (or at least approximately equivalent) in that any motion that can be achieved in one can be achieved in the other (in an appropriate sense). Planning and analysis can then

Abstraction   Symbolic model and planning   Execution of plan
Motion Description Languages and Symbolic Control, Fig. 2 Simple example of symbolic control with a focus on abstracting the system dynamics and environment. The initial environment (*left image*) is segmented into different regions and simple controllers developed for moving from region to region. The image shows two possible controllers: one that actuates the robot through a tight slither pattern to move forward by one region and one that twists the robot to face the cell to the left before slithering across and then reorienting. The combination of regions and actions yields a symbolic abstraction (*center image*) that allows for planning to achieve specific goals, such as moving through the right-hand turn. Executing this plan leads to a physical trajectory of the system (*right image*)

be done on the (simpler) symbolic model. Further details on such schemes can be found in, for example, Tabuada (2006) and Bicchi et al. (2006).

As an illustrative example, consider as before a snakelike robot moving through a right-hand turn. In a simplified view of this second approach to symbolic control, one begins by dividing the environment up into regions and then defining controllers to steer the robot from region to region as illustrated in the left image in Fig. 2. This yields the symbolic model shown in the center of Fig. 2. A plan is then developed on this model to move from the initial position to the final position. This planning step can take into account restrictions on the motion and subgoals of the task. Here, for example, one may want the robot to stay to the right of the double yellow line that is in its lane of traffic. The plan $R_2 \rightarrow R_4 \rightarrow R_6 \rightarrow R_8 \rightarrow R_9 \rightarrow R_{10}$ is one sequence that drives the system around the turn while satisfying the lane requirement. Each transition in the sequence corresponds to a control law. The plan is then executed by applying the sequence of control laws, resulting in the actual trajectory shown in the right image in Fig. 2.

Applications and Connections

The fundamental idea behind symbolic control, namely, mitigating complexity by abstracting a system, its environment, and even the tasks to be accomplished into a simpler but (approximately) equivalent model, is a natural and a powerful one. It has clear connections to both hybrid systems (Brockett 1993; Egerstedt 2002) and to quantized control (Bicchi et al. 2006), and the tools from those fields are often useful in describing and analyzing systems with symbolic representations of the control and of the dynamics. Symbolic control is not, however, strictly a subcategory of either field, and it provides a unique set of tools for the control and analysis of dynamic systems.

Brockett's original MDL was intended to serve as a tool for describing and planning robot motion. Inspired in part by this, languages for motion continue to be developed. Some of these extend and provide a more formal basis for motion programming (Manikonda et al. 1998) and interconnection of dynamic systems into a single whole (Murray et al. 1992), while some are designed for specialized dynamics or applications such as flight vehicles

M

(Frazzoli et al. 2005), self-assembly (Klavins 2007), and other areas. In addition to studying standard systems and control theoretic ideas, including notions of reachability (Bicchi et al. 2002) and stability (Tarraf et al. 2008), the framework of symbolic control introduces interesting questions such as how to understand the reduction of complexity that can be achieved for a given collection of symbols (Egerstedt and Brockett 2003).

While there are many application areas of symbolic control, the one that is perhaps most active is that of motion planning for autonomous mobile robots (Belta et al. 2007). As illustrated in Figs. 1 and 2, symbolic control allows the planning problem (i.e., the determination of how to achieve a desired task) to be separated from the complexities of the dynamics. The approach has been particularly fertile when coupled with symbolic descriptions of the tasks to be achieved. While point-to-point commands are useful, and can be often thought of as symbols themselves from which to build more complicated commands, most tasks that one would want mobile robots to carry out involve combinations of spatial goals (move to a certain location), sequencing (first do this and then do that) or other temporal requirements (repeatedly visit a collection of regions), as well as safety or other restrictions (avoid obstacles or regions that are dangerous for the robot to traverse). Such tasks can be described using a variety of temporal logics. These are, essentially, logic systems that include rules related to time in addition to the standard Boolean operators. These tasks can be combined with a symbolic description of a system and then automated tools used both to check whether the system is able to perform the desired task and to design plans that ensure the system will do so (Fainekos et al. 2009). To ensure that results on the abstract, symbolic system are valid on the original dynamic system, methods exist for guaranteeing the equivalence of the two models, in an appropriate sense (Girard and Pappas 2007).

Summary and Future Directions

Symbolic control proceeds from the basic goal of mitigating the complexity of dynamic systems, especially in real-world scenarios, to yield a simplification of the problems of analysis and control design. It builds upon results from diverse fields while also contributing new ideas to those areas, including hybrid system theory, formal languages and grammars, and motion planning. There are many open, interesting questions that are the subject of ongoing investigations as well as the genesis of future research.

One particularly fruitful direction is that of combining symbolic control with stochasticity. Systems that operate in the real world are subject to noise with respect both to their inputs (noisy actuators) and to their outputs (noisy sensors). Recent work along these lines can be found in the formal methods approach to motion planning and in hybrid systems (Abate et al. 2011; Lahijanian et al. 2012). The fundamental idea is to use a Markov chain, Markov decision process, or similar model as the symbolic abstraction and then, as in all symbolic control, to do the analysis and planning on this simpler model.

Another interesting direction is to address questions of optimality with respect to the symbols and abstractions for a given dynamic system. Of course, the notion of "optimal" must be made clear, and there are several reasonable notions one could define. There is a clear trade-off between the complexity of individual symbols, the number of symbols used in the motion "alphabet," and the complexity in terms of, say, average number of symbols required to code programs that achieve a given set of tasks. The complexity of a necessary alphabet is also related to the variety of tasks the system might need to perform. An autonomous vacuuming robot is likely to need far fewer symbols in its library than an autonomous vehicle that must operate in everyday traffic conditions and respond to unusual events such as traffic jams. The question of the "right" set of symbols can also

be of use in efficient descriptions of motion in domains such as dance (Baillieul and Ozcimder 2012).

It is intuitively clear that to handle complex scenarios and environments, a hierarchical approach is likely needed. Organizing symbols into progressively higher levels of abstraction should allow for more efficient reasoning, planning, and reaction to real-world settings. Such structures already appear in existing works, such as in the behavior-based approach of Brooks (1986), in the extended Motion Description Language in Manikonda et al. (1998), and in the Spatial Semantic Hierarchy of Kuipers (2000). Despite these efforts, there is still a need for a rigorous approach for analyzing and designing symbolic hierarchical systems.

The final direction discussed here is that of the connection of symbolic control to emergent behavior in large groups of dynamic agents. There are a variety of intriguing examples in nature in which large numbers of agents following simple rules produce large-scale, coherent behavior, including in fish schools and termite and ant colonies (Johnson 2002). How can one predict the global behavior that will emerge from a large collection of independent agents following simple rules (symbols)? How can one design a set of symbols to produce a desired collective behavior? While there has been some work in symbolic control for self-assembling systems (Klavins 2007), this general topic remains a rich area for research.

Motion Planning for Marine Control Systems

Andrea Caiti

DII – Department of Information Engineering & Centro "E. Piaggio", ISME – Interuniversity Research Centre on Integrated Systems for the Marine Environment, University of Pisa, Pisa, Italy

Abstract

In this chapter we review motion planning algorithms for ships, rigs, and autonomous marine vehicles. Motion planning includes path and trajectory generation, and it goes from optimized route planning (off-line long-range path generation through operating research methods) to reactive on-line trajectory reference generation, as given by the guidance system. Crucial to the marine systems case is the presence of environmental external forces (sea state, currents, winds) that drive the optimized motion generation process.

Keywords

Configuration space; Dynamic programming; Grid search; Guidance controller; Guidance system; Maneuvering; Motion plan; Optimization algorithms; Path generation; Route planning; Trajectory generation; World space

Introduction

Marine control systems include primarily ships and rigs moving on the sea surface, but also underwater systems, manned (submarines) or unmanned, and eventually can be extended to any kind of off-shore moving platform.

A *motion plan* consists in determining what motions are appropriate for the marine system to reach a goal, or a target/final state (LaValle 2006). Most often, the final state corresponds to a geographical location or destination, to be reached by the system while respecting constraints of physical and/or economical nature. Motion planning in marine systems hence starts from *route planning*, and then it covers desired *path generation* and *trajectory generation*. Path generation involves the determination of an ordered sequence of states that the system has to follow; trajectory generation requires that the states in a path are reached at a prescribed time.

Route, path, and trajectory can be generated off-line or on-line, exploiting the feedback from the system navigation and/or from external sources (weather forecast, etc.). In the feedback case, planning overlaps with the *guidance system*, i.e., the continuous computation of the reference (desired) state to be used as reference input by the motion control system (Fossen 2011).

Formal Definitions and Settings

Definitions and classifications as in Goerzen et al. (2010) and Petres et al. (2007) are followed

throughout the section. The marine systems under considerations live in a physical space referred to as the *world space* (e.g., a submarine lives in a 3-D Euclidean space). A *configuration* q is a vector of variables that define position and orientation of the system in the world space. The set of all possible configurations is the *configuration space*, or *C-space*. The vector of configuration and configuration rate of changes is the *state* of the system $\mathbf{x} = \begin{bmatrix} q^T \dot{q}^T \end{bmatrix}^T$, and the set of all the possible states is the *state space*. The kino-dynamic model associated to the system is represented by the system *state equations*. The regions of *C-space* free from obstacles are called *C-free*.

The *path planning* problem consists in determining a curve $\gamma : [0, 1] \rightarrow C\text{-free}, s \rightarrow \gamma(s)$, with $\gamma(0)$ corresponding to the initial configuration and $\gamma(1)$ corresponding to the goal configuration. Both initial and goal configurations are in *C-free*. The *trajectory planning* problem consists in determining a curve γ and a *time law*: $t \rightarrow s(t)$ *s.t.* $\gamma(s) = \gamma(s(t))$. In both cases, either the path or the trajectory must be compatible with the system state equations. In the following, definitions of motion algorithm properties are given referring to path planning, but the same definitions can be easily extended to trajectory planning.

A motion planning algorithm is *complete* if it finds a path when one exists, and returns a proper flag when no path exists. The algorithm is *optimal* when it provides the path that minimizes some cost function J. The (strictly positive) cost function J is isotropic, when it depends only on the system configuration ($J = J(q)$), or anisotropic, when it depends also on an external force field $\mathbf{f}$ (e.g., sea currents, sea state, weather perturbations) ($J = J(q, \mathbf{f})$). The cost function J induces a *pseudometric* in the configuration space; the distance d between configurations q_1 and q_2 through the path γ is the "cost-to-go" from q_1 to q_2 along γ:

$$d(q_1, q_2) = \int_0^1 J(\gamma_{q_1 q_2}(s), \mathbf{f}) ds \qquad (1)$$

An optimal motion planning problem is:

– *Static* if there is perfect knowledge of the environment at any time, *dynamic* otherwise
– *Time-invariant* when the environment does not evolve (e.g., coastline that limits the *C-free* subspace), *time-variant* otherwise (e.g., other systems – ships, rigs – in navigation)
– *Differentially constrained* if the system state equations act as a constraint on the path, *differentially unconstrained* otherwise

In practice, optimal motion planning problems are solved numerically through discretization of the *C-space*. *Resolution* completeness/optimality of an algorithm implies the achievement of the solution as the discretization interval tends to zero. *Probabilistic* completeness/optimality implies that the probability of finding the solution tends to 1 as the computation time approaches infinity. *Complexity* of the algorithm refers to the computational time required to find a solution as a function of the dimension of the problem.

The scale of the motion w.r. to the scale of the system defines the specific setting of the problem. In cargo ships route planning from one port call to the next, the problem is stated first as static, time-invariant, differentially unconstrained *path* planning problem; once a large-scale route is thus determined, it can be refined on smaller scales, e.g., smoothing it, to make it compatible with ship maneuverability. Maneuvering the same cargo ship in the approaches to a harbor has to be casted as a dynamic, time-variant, differentially constrained *trajectory* planning problem.

Large-Scale, Long-Range Path Planning

Route determination is a typical long-range path planning problem for a marine system. The geographical map is discretized into a grid, and the optimal path between the approaches of the starting and destination ports is determined as a sequence of adjacent grid nodes. The problem is taken as time-invariant and differentially unconstrained, at least in the first stages of the procedure. It is assumed that the ship will cruise at its own (constant) most economical speed to optimize bunker consumption, the major

M

source of operating costs (Wang and Meng 2012). Navigation constraints (e.g., allowed ship traffic corridors for the given ship class) are considered, as well as weather forecasts and predicted/prevailing currents and winds. The cost-to-go Eq. (1) is built between adjacent nodes either in terms of time to travel or in terms of operating costs, both computed correcting the nominal speed with the environmental forces. Optimality is defined in terms of shortest time/minimum operating cost; the anisotropy introduced by sea/weather conditions is the driving element of the optimization, making the difference with respect to straightforward shortest route computation. The approach is iterated, starting with a coarse grid and then increasing grid resolution in the neighborhood of the previously found path.

The most widely used optimization approach for surface ships is *dynamic programming* (LaValle 2006); alternatively, since the determination of the optimal path along the grid nodes is equivalent to a search over a graph, the *A* algorithm* is applied (Delling et al. 2009). As the discretization grid gets finer, system dynamics are introduced, accounting for ship maneuverability and allowing for deviation from the constant ship speed assumption. Dynamic programming allows to include system dynamics at any level of resolution desired; however, when system dynamics are considered, the problem dimension grows from 2-D to 3-D (2-D space plus time).

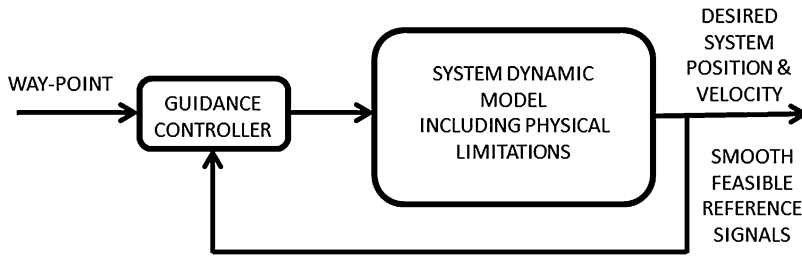
In the case of underwater navigation, path planning takes place in a 3-D world space, and the inclusion of system dynamics makes it a 4-D problem; moreover, bathymetry has to be included as an additional constraint to shape the *C-free* subspace. Dynamic programming may become unfeasible, due to the increase in dimensionality. Computationally feasible algorithms for this case include global search strategies with probabilistic optimality, as *genetic algorithms* (Alvarez et al. 2004), or improved grid-search methods with resolution optimality, as FM* (Petres et al. 2007).

Environmental force fields are intrinsically dynamic fields; moreover, the prediction of such fields at the moment of route planning may be updated as the ship is in transit along the route. The path planning algorithms can/must be rerun, over a grid in the neighborhood of the nominal path, each time new environmental information becomes available. Kino-dynamic model of the ship must be included, allowing for deviation from the established path and ship speed variation around the nominal most economical speed. The latter case is particularly important: increasing/decreasing the speed to avoid a weather perturbation keeping the same route may indeed result in a reduced operating cost with respect to path modifications keeping a constant speed. This implies that the timing over the path must be specified. Dynamic programming is well suited for this transition from path to trajectory generation, and it is still the most commonly used approach to trajectory (re)planning in reaction to environmental predictions update.

When discretizing the world space, the minimum grid size should still be large enough to allow for ship maneuvering between grid nodes. This is required for safety, to allow evasive maneuvering when other ships are at close ranges, and for the generation of smooth, dynamics-compliant trajectories between grid points. This latter aspect bridges motion planning with guidance.

Trajectory Planning, Maneuvering Generation, and Guidance Systems

Once a path has been established over a spatial grid, a continuous reference has to be generated, linking the nodes over the grid. The generation of the reference trajectory has to take into account all the relevant dynamic properties and constraints of the marine system, so that the reference motion is *feasible*. In this scenario, the path/trajectory nodes are *way-points*, and the trajectory generation connects the way-points along the route. The approaches to trajectory generation can be divided between those that do not compute explicitly in advance the whole trajectory and those that do.

Among the approaches that do not need explicit trajectory computation between way-points,


Motion Planning for Marine Control Systems, Fig. 1 Generation of a reference trajectory with a system model and a guidance controller (Adapted from Fossen (2011))

the most common is the *line-of-sight* (LOS) guidance law (Pettersen and Lefeber 2001). LOS guidance can be considered a path generation, more than a trajectory generation, since it does not impose a time law over the path; it computes directly the desired ship reference heading on the basis of the current ship position and the previous and next way-point positions. A review of other guidance approaches can be found in Breivik and Fossen (2008), where maneuvering along the path and steering around the way-points are also discussed. From such a set of different maneuvers, a library of motion primitives can be built (Greytak and Hover 2010), so that any motion can be specified as a sequence of primitives. While each primitive is feasible by construction, an arbitrary sequence of primitives may not be feasible. An optimized search algorithm (dynamic programming, A*) is again needed to determine the optimal feasible maneuvering sequence.

Path/trajectory planning explicitly computing the desired motion among two way-points may include a system dynamic model, or may not. In the latter case, a sufficiently smooth curve that connects two way-points is generated, for instance, as splines or as Dubins paths (LaValle 2006). Curve generation parameters must be set so that the "sufficiently smooth" part is guaranteed. After curve generation, a trim velocity is imposed over the path (path planning), or a time law is imposed, e.g., smoothly varying the system reference velocity with the local curvature radius.

Planners that do use a system dynamic model are described in Fossen (2011) as part of the guidance system. In practice, the dynamic model

is used in simulation, with a (simulated) feedback controller (*guidance controller*), the next way-point as input, and the (simulated) system position and velocity as output. The simulated results are feasible maneuvers by construction and can be given as reference position/velocity to the physical control system (Fig. 1).

Summary and Future Directions

Motion planning for marine control systems employs methodological tools that range from operating research to guidance, navigation, and control systems. A crucial role in marine applications is played by the anisotropy induced by the dynamically changing environmental conditions (weather, sea state, winds, currents – the external force fields). The quality of the plan will depend on the quality of environmental information and predictions.

While motion planning can be considered a mature issue for ships, rigs, and even standalone autonomous vehicles, current and future research directions will likely focus on the following items:

– Coordinated motion planning and obstacle avoidance for *teams* of autonomous surface and underwater vehicles (Aguiar and Pascoal 2012; Casalino et al. 2009)
– Naval traffic regulation compliant maneuvering in restricted spaces and collision evasion maneuvering (Tam and Bucknall 2010)
– Underwater intervention robotics (Antonelli 2006; Sanz et al. 2010)

Motion Planning for PDEs

Thomas Meurer
Faculty of Engineering,
Christian-Albrechts-University Kiel, Kiel,
Germany

Abstract

Motion planning refers to the design of an open-loop or feedforward control to realize prescribed desired paths for the system states or outputs. For distributed-parameter systems described by partial differential equations (PDEs), this requires to take into account the spatial-temporal system dynamics. Here, flatness-based techniques provide

a systematic inversion-based motion planning approach, which is based on the parametrization of any system variable by means of a flat or basic output. With this, the motion planning problem can be solved rather intuitively as is illustrated for linear and semilinear PDEs.

Keywords

Basic output; Flatness; Formal integration; Formal power series; Trajectory assignment; Trajectory planning; Transition path

Introduction

Motion planning or trajectory planning refers to the design of an open-loop control to realize prescribed desired temporal or spatial-temporal paths for the system states or outputs. Examples include smart structures with embedded actuators and sensors such as adaptive optics in telescopes, adaptive wings or smart skins, thermal and reheating processes in steel industry, and deep drawing, start-up, shutdown, or transitions between operating points in chemical engineering, as well as multi-agent deployment and formation control (see, e.g., the overview in Meurer 2013).

For the solution of the motion planning and tracking control problem for finite-dimensional linear and nonlinear systems, differential flatness as introduced in Fliess et al. (1995) has evolved into a well-established inversion-based technique. Differential flatness implies that any system variable can be parametrized in terms of a flat or a so-called basic output and its time derivatives up to a problem-dependent order. As a result, the assignment of a suitable desired trajectory for the flat output directly yields the respective state and input trajectories to realize the prescribed motion. Flatness can be adapted to systems governed by partial differential equations (PDEs). For this, different techniques have been developed utilizing operational calculus or spectral theory for linear PDEs, (formal) power series for linear PDEs, and PDEs involving polynomial

nonlinearities as well as formal integration for semilinear PDEs using a generalized Cauchy-Kowalevski approach. To illustrate the principle ideas and the evolving research results starting with Fliess et al. (1997), subsequently different techniques are introduced based on selected example problems. For this, the exposition is primarily restricted to parabolic PDEs with a brief discussion of motion planning for hyperbolic PDEs before concluding with possible future research directions.

Linear PDEs

In the following, a scalar linear diffusion-reaction equation is considered in the state variable $x(z, t)$ with boundary control $u(t)$ governed by

$$\partial_t x(z, t) = \partial_z^2 x(z, t) + r x(z, t) \qquad \text{(1a)}$$

$$\partial_z x(0, t) = 0, \quad x(1, t) = u(t) \qquad \text{(1b)}$$

$$x(z, 0) = 0. \qquad \text{(1c)}$$

This PDE describes a wide variety of thermal and fluid systems including heat conduction and tubular reactors. Herein, $r \in \mathbb{R}$ refer to the reaction coefficient and the initial state is without loss of generality assumed zero. In order to solve the motion planning problem for (1), a feedforward control $t \mapsto u^*(t)$ is determined to realize a finite-time transition between the initial state and a final stationary state $x_T^*(z)$ to be imposed for $t \geq T$.

Formal Power Series
By making use of the formal power series expansion of the state variable

$$x(z, t) \to \hat{x}(z, t) = \sum_{n=0}^{\infty} \hat{x}_n(t) \frac{z^n}{n!} \qquad \text{(2)}$$

the evaluation of (1) results in the 2nd-order recursion

$$\hat{x}_n(t) = \partial_t \hat{x}_{n-2}(t) - r x_{n-2}(t), \quad n \geq 2 \quad \text{(3a)}$$

$$\hat{x}_1(t) = 0. \qquad \text{(3b)}$$

In order to be able to solve (3) for $\hat{x}_n(t)$, it is hence required to impose $\hat{x}_0(t) = \hat{x}(0,t)$. Denoting $y(t) = x(0,t)$ or respectively

$$\hat{x}_0(t) = y(t) \tag{3c}$$

implies

$$\hat{x}_{2n}(t) = (\partial_t - r)^n \circ y(t), \quad \hat{x}_{2n+1}(t) = 0. \tag{4}$$

Hence, any series coefficient in (2) can be differentially parametrized by means of $y(t)$. Taking into account the inhomogeneous boundary condition in (1b), i.e.,

$$u(t) = x(1,t) = \sum_{n=0}^{\infty} \frac{x_n(t)}{n!} = \sum_{n=0}^{\infty} \frac{x_{2n}(t)}{(2n)!} \tag{5}$$

yields that $y(t) = x(0,t)$ can be considered as a flat or basic output. In particular, by prescribing a suitable trajectory $t \mapsto y^*(t) \in C^\infty(\mathbb{R})$ for $y(t)$, the evaluation of (5) yields the feedforward control $u^*(t)$ which is required to realize the spatial-temporal path $x^*(z,t)$ obtained from the substitution of $y^*(t)$ into (2) with coefficients parametrized by (4). This, however, relies on the uniform convergence of (2) in view of (4) with at least a unit radius of convergence in z. For this, the notion of a Gevrey class function is needed (Rodino 1993).

Definition 1 (Gevrey class) The function $y(t)$ is in $G_{D,\alpha}(\Lambda)$, the Gevrey class of order α in $\Lambda \subseteq \mathbb{R}$, if $y(t) \in C^\infty(\Lambda)$ and for every closed subset Λ' of Λ there exists a $D > 0$ such that $\sup_{t \in \Lambda'} |\partial_t^n y(t)| \le D^{n+1}(n!)^\alpha$.

The set $G_{D,\alpha}(\Lambda)$ forms a linear vector space and a ring with respect to the arithmetic product of functions which is closed under the standard rules of differentiation. Gevrey class functions of order $\alpha < 1$ are entire and are analytic if $\alpha = 1$.

Theorem 1 Let $y(t) \in G_{D,\alpha}(\mathbb{R})$ for $\alpha < 2$, then the formal power series (2) with coefficients (4) converges uniformly with infinite radius of convergence.

The proof of this result can be, e.g., found in Laroche et al. (2000) and Lynch and Rudolph (2002) and relies on the analysis of the recursion (3) taking into account the assumptions on the function $y(t)$.

Trajectory Assignment

To apply these results for the solution of the motion planning problem to achieve finite-time transitions between stationary profiles, it is crucial to properly assign the desired trajectory $y^*(t)$ for the basic output $y(t)$. For this, observe that stationary profiles $x^s(z) = x^s(z; y^s)$ are due to the flatness property (Classically stationary solutions are to be defined in terms of stationary input values $x^s(1) = u^s$.) governed by

$$0 = \partial_z^2 x^s(z) + r x^s(z) \tag{6a}$$

$$\partial_z x^s(0) = 0, \quad x^s(0) = y^s. \tag{6b}$$

Hence, assigning different y^s results in different stationary profiles $x^s(z; y^s)$. The connection between an initial stationary profile $x_0^s(z; y_0^s)$ and a final stationary profile $x_T^s(z; y_T^s)$ is achieved by assigning $y^*(t)$ such that

$$y^*(0) = y_0^s, \qquad y^*(T) = y_T^s$$
$$\partial_t^n y^*(0) = 0, \qquad \partial_t^n y^*(T) = 0, \quad n \ge 1.$$

This implies that $y^*(t)$ has to be locally nonanalytic at $t \in \{0, T\}$ and in view of the previous discussion has thus to be a Gevrey class function of order $\alpha \in (1, 2)$. For specific problems different functions have been suggested fulfilling these properties. In the following, the ansatz

$$y^*(t) = y_0^s + (y_T^s - y_0^s)\Phi_{T,\gamma}(t) \tag{7a}$$

is used with

$$\Phi_{T,\gamma}(t) = \begin{cases} 0, & t \le 0 \\ \frac{\int_0^t h_{T,\gamma}(\tau)\mathrm{d}\tau}{\int_0^T h_{T,\gamma}(\tau)\mathrm{d}\tau} & t \in (0, T) \\ 1, & t \ge T \end{cases} \tag{7b}$$

for $h_{T,\gamma}(t) = \exp\left(-[t/T(1 - t/T)]^{-\gamma}\right)$ if $t \in (0, T)$ and $h_{T,\gamma}(t) = 0$ else. It can be shown that

Motion Planning for PDEs, Fig. 1 Simulated spatial-temporal transition path (*top*) and applied flatness-based feedforward control $u^*(t)$ and desired trajectory $y^*(t)$ (*bottom*) for (1)

(7b) is a Gevrey class function of order $\alpha = 1 + 1/\gamma$ (Fliess et al. 1997). Alternative functions are presented, e.g., in Rudolph (2003).

Simulation Example

In order to illustrate the results of the motion planning procedure described above, let $r = -1$ in (1). The differential parametrization (4) of the series coefficients is evaluated for the desired trajectory $y^*(t)$ defined in (7) for $y_0^s = 0$ and $y_T^s = 1$ with the transition time $T = 1$ and the parameter $\gamma = 2$. With this, the finite-time transition between the zero initial stationary profile $x_0^*(z) = 0$ and the final stationary profile $x_T^*(z) = x_T^s(z) = y_T^s \cosh(z)$ is realized along the trajectory $x(0, t) = y^*(t)$. The corresponding

feedforward control and spatial-temporal transition path are shown in Fig. 1.

Extensions and Generalizations

The previous considerations constitute a first systematic approach to solve motion planning problems of systems governed by PDEs. The underlying techniques can be, however, further generalized to address coupled systems of PDEs, certain classes of nonlinear PDEs (see also section "Semilinear PDEs"), or in-domain control.

While the application of formal power series is restricted to boundary control diffusion-convection-reaction systems, the approach can be combined with so-called resummation techniques to overcome convergence issues such as slowly

converging or even divergent series expansions (Laroche et al. 2000; Meurer and Zeitz 2005).

Flatness-based techniques for motion planning can be also embedded into an operator theoretic context using semigroup theory by restricting the analysis to so-called Riesz spectral operators. This enables to analyze coupled systems of linear PDEs with both boundary and in-domain control in a single and multiple spatial coordinates with a common framework (Meurer 2011, 2013). In addition, experimental results for flexible beam and plate structures with embedded piezoelectric actuators confirm the applicability of this design approach and the achievable high tracking accuracy when transiently shaping the deflection profile (Schröck et al. 2013).

Semilinear PDEs

Flatness can be extended to semilinear PDEs. This is subsequently illustrated for the diffusion-reaction system

$$\partial_t x(z, t) = \partial_z^2 x(z, t) + r(x(z, t)) \qquad (8a)$$

$$\partial_z x(0, t) = 0, \quad x(1, t) = u(t) \qquad (8b)$$

$$x(z, 0) = 0 \qquad (8c)$$

with boundary input $u(t)$. Similar to the previous section, the motion planning problem refers to the determination of a feedforward control $t \mapsto u^*(t)$ to realize finite-time transitions starting at the initial profile $x_0^*(z) = x(z, 0) = 0$ to achieve a final stationary profile $x_T^*(z)$ for $t \geq T$.

Formal Power Series
If $r(x(z, t))$ is a polynomial in $x(z, t)$ or an analytic function, then similar to the previous section, formal power series can be applied to solve the motion planning problem. This, however, relies on the successive evaluation of Cauchy's product formula. As an example, consider

$$r(x(z, t)) = r_1 x(z, t) + r_2 x^2(z, t),$$

then the formal power series ansatz (2) results in the recursion

$$\hat{x}_n(t) = \partial_t \hat{x}_{n-2}(t) - r_1 x_{n-2}(t)$$
$$- r_2 \sum_{j=0}^{n-2} \binom{n}{j} \hat{x}_j(t) \hat{x}_{n-j}(t), \quad n \geq 2 \qquad (9a)$$

$$\hat{x}_1(t) = 0. \qquad (9b)$$

Similar to the linear setting in the section "Linear PDEs" above, the recursion can be solved for $\hat{x}_n(t)$ by imposing $\hat{x}_0(t) = \hat{x}(0, t)$ or respectively

$$\hat{x}_0(t) = y(t). \qquad (9c)$$

As a result, also in this nonlinear setting any series coefficient can be expressed in terms of $y(t)$ and its time derivatives. Hence, $y(t) = x(0, t)$ denotes a basic output for the semilinear PDE (8). The uniform series convergence can be analyzed by restricting any trajectory $y(t)$ to a certain Gevrey order α while simultaneously restricting the absolute values of d, r_1 and r_2 (Dunbar et al. 2003; Lynch and Rudolph 2002). These restrictions can be approached using, e.g., resummation techniques to sum slowly converging or divergent series to a meaningful limit. The reader is therefore referred to Meurer and Zeitz (2005) or Meurer and Krstic (2011), with the latter introducing a PDE-based approach for formation control of multi-agent systems.

Formal Integration
A generalization of these results has been recently suggested in Schörkhuber et al. (2013) by making use of an abstract Cauchy-Kowalevski theorem in Gevrey classes. In order to illustrate this, solve (8a) for $\partial_z^2 x(z, t)$ and formally integrate with respect to z taking into account the boundary conditions (8b). This yields the implicit solution

$$x(z, t) = x_+(0, t) \int_0^z \int_0^p \big[\partial_t x(q, t)$$
$$- r(x(q, t)) \big] \mathrm{d}q \, \mathrm{d}p \qquad (10a)$$

$$u(t) = x(1, t), \qquad (10b)$$

which can be used to develop to a flatness-based design systematics for motion planning given semilinear PDEs. For this, introduce

$$y(t) = x(0, t), \tag{11}$$

and rewrite (10b) in terms of the sequence of functions $(x^{(n)}(z, t))_{n=0}^{\infty}$ according to

$$x^{(0)}(z, t) = y(t) \tag{12a}$$

$$x^{(n+1)}(z, t) = x^{(0)}(z, t) + \int_0^z \int_0^p \big[\partial_t x^{(n)}(q, t)$$

$$-r(x^{(n)}(q, t))\big] \mathrm{d}q \mathrm{d}p. \tag{12b}$$

From this, it is obvious that $y(t)$ denotes a basic output differentially parametrizing the state variable $x(z, t) = \lim_{n \to \infty} x^{(n)}(z, t)$ and the boundary input $u(t) = x(1, t)$ provided that the limit exists as $n \to \infty$. As is shown in Schörkhuber et al. (2013) by making use of scales of Banach spaces in Gevrey classes and abstract Cauchy-Kowalevski theory, the convergence of the parametrized sequence of functions $(x^{(n)}(z, t))_{n=0}^{\infty}$ can be ensured in some compact subset of the domain $z \in [0, 1]$. Besides its general setup this approach provides an iteration scheme, which can be directly utilized for a numerically efficient solution of the motion planning problem.

Simulation Example

Let the reaction be subsequently described by

$$r(x(z, t)) = \sin(2\pi x(z, t)). \tag{13}$$

The iterative scheme (12) is evaluated for the desired trajectory $y^*(t)$ defined in (7) for $y_0^s = 0$ and $y_T^s = 1$ with the transition time $T = 1$ and the parameter $\gamma = 1$, i.e., the desired trajectory is of Gevrey order $\alpha = 2$. The resulting feedforward control $u^*(t)$ and the spatial-temporal transition path resulting from the numerical solution of the PDE are depicted in Fig. 2. The desired finite-time transition between the zero initial stationary profile $x_0^*(z) = 0$ and the final stationary profile $x_T^*(z) = x_T^s(z)$ determined by

$$0 = \partial_z^2 x^s(z) + r(x^s(z)) \tag{14a}$$

$$\partial_z x^s(0) = 0, \quad x^s(0) = y^s. \tag{14b}$$

is clearly achieved along the prescribed path $y^*(t)$.

Extensions and Generalizations

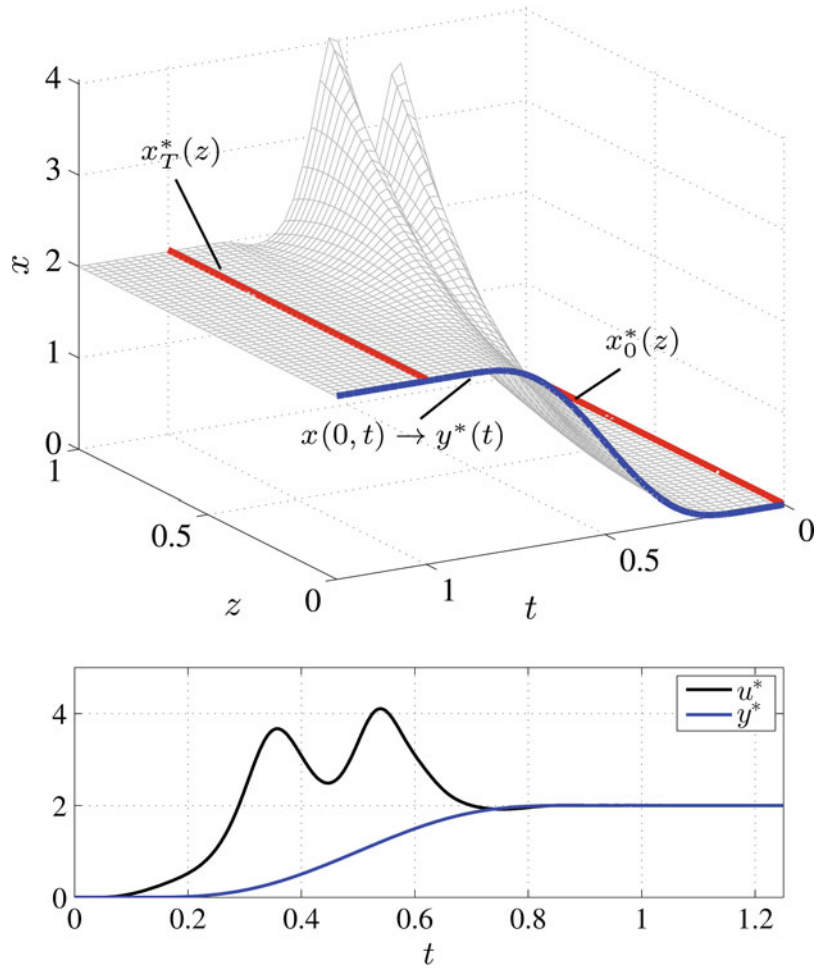
Generalizations of the introduced formal integration approach to solve motion planning problems for systems of coupled PDEs are, e.g., provided in Schörkhuber et al. (2013). Moreover, linear diffusion-convection-reaction systems with spatially and time-varying coefficients defined on a higher-dimensional parallelepipedon are addressed in Meurer and Kugi (2009) and Meurer (2013).

Hyperbolic PDEs

Hyperbolic PDEs exhibiting wavelike dynamics require the development of a design systematics explicitly taking into account the finite speed of wave propagation. For linear hyperbolic PDEs, operational calculus has been successfully applied to determine the state and input parametrizations in terms of the basic output and its advanced and delayed arguments (Petit and Rouchon 2001, 2002; Rouchon 2001; Rudolph and Woittennek 2008; Woittennek and Rudolph 2003). In addition, the method of characteristics can be utilized to address both linear and quasi-linear hyperbolic PDEs. Herein, a suitable change of coordinates enables to reformulate the PDE in a normal form, which can be (formally) integrated in terms of a basic output. With this, also an efficient numerical procedure can be developed to solve motion planning problems for hyperbolic PDEs (Woittennek and Mounier 2010).

Summary and Future Directions

Motion planning constitutes an important design step when solving control problems for systems governed by PDEs. This is particularly due to

Motion Planning for PDEs, Fig. 2 Simulated spatial-temporal transition path (*top*) and applied flatness-based feedforward control $u^*(t)$ and desired trajectory $y^*(t)$ (*bottom*) for (8) with (13)


the increasing demands on quality, accuracy, and efficiency, which require to turn away from the pure stabilization of an operating point toward the realization of specific start-up, transition, or tracking tasks. In view of these aspects, future research directions might deepen and further evolve the following:

– Semi-analytic design techniques taking into account suitable approximation schemes for complex-shaped spatial domains
– Nonlinear PDEs and coupled systems of nonlinear PDEs with boundary and in-domain control
– Applications arising, e.g., in aeroelasticity, micromechanical systems, fluid flow, and fluid-structure interaction.

Motorcycle Dynamics and Control

Martin Corless
School of Aeronautics & Astronautics, Purdue University, West Lafayette, IN, USA

Abstract

A basic model due to Sharp which is useful in the analysis of motorcycle behavior and control is developed. This model is based on linearization of a bicycle model introduced by Whipple, but is augmented with a tire model in which the lateral tire force depends in a dynamic fashion on tire behavior. This model is used to explain some of the important characteristics of motorcycle behavior. The significant dynamic modes exhibited by this model are capsize, weave, and wobble.

Keywords

Bicycle; Capsize; Counter-steering; Motorcycle; Single-track vehicle; Tire model; Weave; Wobble
M

Introduction

The bicycle is mankind's ultimate solution to the quest for a human-powered vehicle (Herlihy 2006). The motorcycle just makes riding more fun. Bicycles, motorcycles, scooters, and mopeds are all examples of single-track vehicles and have similar dynamics. The dynamics of a motorcycle are considerably more complicated than that of a four-wheel vehicle such as a car. The first obvious difference in behavior is stability. An unattended upright stationary motorcycle is basically an inverted pendulum and is unstable about its normal upright position, whereas a car has no stability issues in the same configuration. Another difference is that a motorcycle must lean when cornering. Although a car leans a little due to suspension travel, there is no necessity for it to lean in cornering. A perfectly rigid car would not lean. Furthermore, beyond low speeds, the steering behavior of a

motorcycle is not intuitive like that of a car. To turn a car right, the driver simply turns the steering wheel right; on a motorcycle, the rider initially turns the handlebars to the left. This is called counter-steering and is not intuitive.

A Basic Model

To obtain a basic motorcycle model, we start with four rigid bodies: the rear frame (which includes a rigidly attached rigid rider), the front frame (includes handlebars and front forks), the rear wheel, and the front wheel; see Fig. 1. We assume that both frames and wheels have a plane of symmetry which is vertical when the bike is in its nominal upright configuration. The front frame can rotate relative to the rear frame about the steering axis; the steering axis is in the plane of symmetry of each frame and in the nominal upright configuration of the bike, the angle it makes with the vertical is called the rake angle or caster angle and is denoted by ϵ. The rear wheel rotates relative to the rear frame about an axis perpendicular to the rear plane of symmetry and is symmetrical with respect to this axis. The same relationship holds between the front wheel and the front frame. Although each wheel can be three dimensional, we model the wheels as terminating in a knife edge at their boundaries and contact the ground at a single point. Points Q and P are the points on the ground in contact with the front and rear wheels, respectively.

Each of the above four bodies are described by their mass, mass center location, and a 3×3 inertia matrix. Two other important parameters are the wheelbase w and the trail c. The wheelbase is the distance between the contact points of the two wheels in the nominal configuration, and the trail is the distance from the front wheel contact point Q to the intersection S of the steering axis with the ground. The trail is normally positive, that is, Q is behind S. The point G locates the mass center of the complete bike in its nominal configuration, whereas G_A is the location of the mass center of the front assembly (front frame and wheel).

Description of Motion

Considering a right-handed reference frame $e = (\hat{e}_1, \hat{e}_2, \hat{e}_3)$ with origin O fixed in the ground, the bike motion can be described by the location of the rear wheel contact point P relative to O, the orientation of the rear frame relative to e, and the orientation of the front frame relative to the rear frame; see Fig. 2. Assuming the bike is moving along a horizontal plane, the location of P is usually described by Cartesian coordinates x and y. Let reference frame b be fixed in the rear frame with $\hat{b}_1$ and $\hat{b}_3$ in the plane of symmetry with $\hat{b}_1$ along the nominal $P - S$

Motorcycle Dynamics and Control, Fig. 1 Basic model
Motorcycle Dynamics and Control, Fig. 2 Description of motion

line; see Fig. 2. Using this reference frame, the orientation of the rear frame is described by a 3-1-2 Euler angle sequence which consists of a yaw rotation by ψ about the 3-axis followed by a lean (roll) rotation by ϕ about the 1-axis and finally by a pitch rotation by θ about the 2-axis. The orientation of the front frame relative to the rear frame can be described by the steer angle δ. Assuming both wheels remain in contact with the ground, the pitch angle θ is not independent; it is uniquely determined by δ and ϕ. In considering small perturbations from the upright nominal configuration, the variation in pitch is usually ignored. Here we consider it to be zero. Also the dynamic behavior of the bike is independent of the coordinates x, y, and ψ. These coordinates can be obtained by integrating the velocity of P and $\dot{\psi}$.

The Whipple Bicycle Model

The "simplest" model which captures all the salient features of a single track vehicle for a basic understanding of low-speed dynamics and control is that originally due to Whipple (1899). We consider the linearized version of this model which is further expounded on in Meijaard et al. (2007). The salient feature of this model is that there is no slip at each wheel. This means that the velocity of the point on the wheel which is instantaneously in contact with the ground is zero; this is illustrated in Fig. 3 for the rear wheel. No slip implies that there is no sideslip which means that the velocity of the wheel contact point ($\bar{v}^P$ in Fig. 3) is parallel to the intersection of the wheel plane with the ground plane; the wheel contact point is the point moving along the ground which is in contact with the wheel.

The rest of this entry is based on linearization of motorcycle dynamics about an equilibrium configuration corresponding to the bike traveling upright in a straight line at constant forward speed $v := v^P$, the speed of the rear wheel contact point P. In the linearized system, the longitudinal dynamics are independent of the lateral dynamics, and in the absence of driving or braking forces, the speed v is constant.

With no sideslip at both wheels, kinematical considerations (see Fig. 4) show that the yaw rate $\dot{\psi}$ is determined by δ; specifically for small angles we have the following linearized relationship:

$$\dot{\psi} = \nu v \delta + \mu \dot{\delta} \qquad (1)$$

where $\nu = c_\epsilon / w$, $c_\epsilon = \cos \epsilon$, and $\mu = c c_\epsilon / w$ is the normalized mechanical trail. In Fig. 4, $\delta_f = c_\epsilon \delta$ is the effective steer angle; it is the angle between the intersections of the front wheel plane and the rear frame plane with the ground. Thus we can completely describe the lateral bike dynamics with the roll angle ϕ and the steer angle δ. To obtain the above relationship, first note that, as a consequence of no sideslip, $\bar{v}^P = v \hat{b}_1$ and $\bar{v}^Q$ is perpendicular to $\hat{f}_2$. Taking the dot product of the expression,
$$\bar{v}^Q = \bar{v}^P + (w+c)\dot{\psi}\, \hat{b}_2 - c(\dot{\psi} + \dot{\delta}_f)\hat{f}_2,$$

with $\hat{f}_2$ while noting that $\hat{b}_1 \cdot \hat{f}_2 = -\sin \delta_f$ and $\hat{b}_2 \cdot \hat{f}_2 = \cos \delta_f$ results in
$$0 = -v \sin \delta_f + (w + c)\dot{\psi} \cos \delta_f - c(\dot{\psi} + \dot{\delta}_f).$$

Linearization about $\delta = 0$ yields the desired result.

The relationship in (1) also holds for four wheel vehicles. There one can achieve a desired

Motorcycle Dynamics and Control, Fig. 3 No slip: $v^{P'} = 0$

Motorcycle Dynamics and Control, Fig. 4 Some kinematics

Motorcycle Dynamics and Control, Fig. 5 Inverted pendulum with accelerating support point

constant yaw rate $\dot{\psi}_d$ by simply letting the steer angle $\delta = \dot{\psi}_d/vv$. However, as we shall see, a motorcycle with its steering fixed at a constant steer angle is unstable. Neglecting gyroscopic terms, it is simply an inverted pendulum. With its steering free, a motorcycle can be stable over a certain speed range and, if unstable, can be easily stabilized above a very low speed by most people. Trials riders can stabilize a motorcycle at any speed including zero.

To help understand the effect of steer angle on bike behavior, we initially ignore the mass and inertia of the front assembly along with gyroscopic effects, and we assume that the $\hat{b}_1$ axis is a principle axis of inertia of the rear frame with moment of inertia I_{xx}. Angular momentum considerations about the $\hat{b}_1$ axis and linearization results in

$$I_{xx}\ddot{\phi} + mha^B = mgh\phi + (N_f c_\epsilon c)\delta \quad (2)$$

where N_f is the normal force (vertical and upwards) on the front wheel and a^B is the lateral acceleration (perpendicular to rear frame) of point B which is the projection of G onto the $\hat{b}_1$ axis. By considering a moment balance about the pitch axis $\hat{b}_2$ through P, one can obtain that $N_f = mgb/w$. Notice that, with the steering fixed at $\delta = 0$, Eq. (2) is the equation of motion of a simple inverted pendulum whose support axis is accelerating horizontally with acceleration a^B. This is illustrated in Fig. 5.

Basic kinematics reveal that $a^B = v\dot{\psi} + b\ddot{\psi}$ and, recalling relationship (1), Eq. (2) now yields the lean equation:

$$\boxed{I_{xx}\ddot{\phi} - mgh\phi = -m_{\phi\delta}\ddot{\delta} - c_{\phi\delta}v\dot{\delta} - k_{\phi\delta}(v)\delta}$$
$$(3)$$

where $m_{\phi\delta} = \mu mhb > 0$, $c_{\phi\delta} = mh(\mu + bv) > 0$ and $k_{\phi\delta}(v) = -\mu mgb + mhvv^2$. Note that v is a constant parameter corresponding to the nominal speed of the rear wheel contact point.

With $\delta = 0$, we have a system whose behavior is characterized by two real eigenvalues: $\pm\sqrt{mgh/I_{xx}}$. This system is unstable due to the positive eigenvalue $\sqrt{mgh/I_{xx}}$. For v sufficiently large, the coefficient $k_{\phi\delta}(v)$ is positive and one can readily show that the above system can be stabilized with positive feedback $\delta = K\phi$ provided $K > mgh/k_{\phi\delta}(v)$. This helps explain the stabilizing effect of a rider turning the handlebars in the direction the bike is falling. Actually, the rider input is a **steer torque** T_δ about the steer axis.

To explain why an uncontrolled motorcycle can be stable or easily stabilized, one also has to look at the effect that ϕ has on δ; in general, a lean perturbation results in the front assembly turning in the same direction, that is, a positive perturbation of ϕ results in a positive change in δ.

The lean equation also explains why a motorcycle must lean when cornering above a certain speed. Suppose the motorcycle is in a right hand corner of radius R at some constant speed v: in this scenario, $\dot{\psi} = v/R$ and, with δ constant, (1) implies that $\delta = \dot{\psi}/vv = 1/vR$; with δ and ϕ constant, the lean equation now requires that $\phi = k_{\phi\delta}(v)\delta/mgh = k_{\phi\delta}(v)/mghvR$. For higher speeds, $k_{\phi\delta}(v) \approx mhvv^2$; hence $\phi \approx v^2/gR$. Since $a^B = v^2/R$, the lean angle ϕ is approximately a^B/g. Hence, to corner with a lateral acceleration $a^B = v^2/R$, the motorcycle must lean at an angle of approximately a^B/g.

The lean equation can also help explain **counter-steering**; that is, at speeds above a reasonably low speed, one can initiate a turn by turning the handlebars in the opposite direction to which one wants to go; to turn right, one initially turns the handlebars to the left. See Limebeer and Sharp (2006) for further discussion.

Taking into account the mass and inertia of the front assembly, gyroscopic effects and cross products of inertia of the rear frame, one can

show (see Meijaard et al. 2007) that the lean equation (3) still holds with

$$m_{\phi\delta} = \mu I_{xz} + I_{A\epsilon x}$$

$$c_{\phi\delta} = \mu m h + v I_{xz} + \mu S_T + c_\epsilon S_F$$

$$k_{\phi\delta}(v) = k_{0\phi\delta} + k_{2\phi\delta} v^2$$

$$k_{0\phi\delta} = -S_A g,$$

$$k_{2\phi\delta} = v(mh + S_T)$$

Here I_{xx} is the moment of inertia of the total motorcycle and rider in the nominal configuration about the $\hat{b}_1$ axis and I_{xz} is the inertia cross product w.r.t the $\hat{b}_1$ and $\hat{b}_3$ axes. The term $I_{A\epsilon x}$ is the front assembly inertia cross product with respect to the steering axis and the $\hat{b}_1$ axis; see Meijaard et al. (2007) for a further description of this parameter. Also, $S_A = \mu m b + m_A u_A$ where m_A is the mass of the front assembly (front wheel and front frame) and u_A is the offset of the mass center of the front assembly from the steering axis, that is, the distance of this mass center from the steering axis; see Fig. 1. The terms $S_F = I_{Fyy}/r_F$ and $S_T = I_{Ryy}/r_R + I_{Fyy}/r_F$ are gyroscopic terms due the rotation of the front and rear wheels where r_F and r_R are the radii of the front and rear wheels, while I_{Fyy} and I_{Ryy} are the moments of inertias of the front and rear wheels about their axles. It is assumed that the mass center of each wheel is located at its geometric center.

By considering an angular momentum balance about a vertical axis through P, one can obtain an expression for the lateral force at the front wheel. Angular momentum considerations about the steering axis for the front assembly and linearization then yield the steer equation:

$$\boxed{\begin{array}{c} m_{\delta\phi}\ddot{\phi} + m_{\delta\delta}\ddot{\delta} + v c_{\delta\phi}\dot{\phi} + v c_{\delta\delta}\dot{\delta} \\ + k_{\delta\phi}\phi + k_{\delta\delta}(v)\delta = T_\delta \end{array}} \quad (4)$$

where

$$m_{\delta\phi} = m_{\phi\delta}$$

$$m_{\delta\delta} = I_{A\epsilon\epsilon} + 2\mu I_{A\epsilon z} + \mu^2 I_{zz}$$

$$k_{\phi\delta} = k_{\delta\phi}$$

$$k_{\delta\delta}(v) = k_{0\delta\delta} + k_{2\delta\delta} v^2$$

$$k_{0\delta\delta} = -s_\epsilon S_A g,$$

$$k_{2\delta\delta} = v(S_A + s_\epsilon S_F)$$

$$c_{\delta\phi} = -(\mu S_T + c_\lambda S_F)$$

$$c_{\delta\delta} = \mu (S_A + v I_{zz}) + v I_{A\epsilon z}$$

Here, I_{zz} is the moment of inertia of the total motorcycle and the rider in the nominal configuration about the $\hat{b}_3$ axis, $I_{A\epsilon\epsilon}$ is the moment of inertia of the front assembly about the steering axis, and $I_{A\epsilon z}$ is the front assembly inertia cross product with respect to the steering axis and the vertical axis through P. The lean equation (3) combined with the steer equation (4) provide an initial model for motorcycle dynamics. This is a linear model with the nominal speed v as a constant parameter and the rider's steering torque T_δ as an input.

Modes of Whipple Model

At $v = 0$, the linearized Whipple model (3)–(4) has two pairs of real eigenvalues: $\pm p_1, \pm p_2$ with $p_2 > p_1 > 0$; see Fig. 6. The pair $\pm p_1$ roughly describe inverted pendulum behavior of the whole bike with fixed steering, while $\pm p_2$ describe inverted pendulum behavior of the front assembly with the rear frame fixed upright. As v increases the real eigenvalues corresponding to p_1 and p_2 meet and from there on form a

Motorcycle Dynamics and Control, Fig. 6 Variation of eigenvalues of Whipple model with speed v

complex conjugate pair of eigenvalues which result in a single oscillatory mode called the **weave mode**. Initially the weave mode is unstable, but is stable above a certain speed v_w, and for large speeds, its eigenvalues are roughly a linear function of v; thus it becomes more damped and its frequency increases with speed. The eigenvalue corresponding to $-p_2$ remains real and becomes more negative with speed; this is called the **castor** mode, because it roughly corresponds to the front assembly castoring about the steer axis. The eigenvalue corresponding to $-p_1$ also remains real but increases, eventually becoming slightly positive above some speed v_c, resulting in an unstable system; the corresponding mode is called the **capsize** mode. Thus the bike is stable in the autostable speed range (v_w, v_c) and unstable outside this speed range. However, above v_c, the unstable capsize mode is easily stabilized by a rider and usually without conscious effort. This is because the time constant of the unstable capsize mode is very small (Astrom et al. 2005).

Sharp71 Model

The Whipple bicycle model is not applicable at higher speeds. In particular, it does not contain a **wobble mode** which is common to bicycle and motorcycle behavior at higher speeds (Sharp 1971). A wobble mode is characterized mainly by oscillation of the front assembly about the steering axis and can sometimes be unstable. Also, in a real motorcycle, the damping and frequency of the weave mode do not continually increase with speed; the damping usually starts to decrease after a certain speed; sometimes this mode even becomes unstable. At higher speeds, one must depart from the simple non-slipping wheel model. In the Whipple model, the lateral force F on a wheel is simply that force which is necessary to maintain the non-holonomic constraint which requires the velocity of the wheel contact point to be parallel to the wheel plane, that is, no sideslip. Actual tires on wheels slip in the longitudinal and lateral direction, and the lateral force depends on slip in the lateral direction, that is, sideslip. This lateral slip is defined

Motorcycle Dynamics and Control, Fig. 7 Lateral force, slip angle, and camber angle

by the **slip angle** α which is the angle between the contact point velocity and the intersection of the wheel plane and the ground; see Fig. 7.

The lateral force also depends on the tire **camber angle** which is the roll angle of the tire; motorcycle tires can achieve large camber angles in cornering; modern MotoGP racing motorcycles can achieve camber angles of nearly 65°. Thus an initial linear model of a tire lateral force is given by

$$F = N(-k_\alpha \alpha + k_\phi \phi) \qquad (5)$$

where N is the normal force on the tire, $k_\alpha > 0$ is called the tire **cornering stiffness**, and $k_\phi > 0$ is called the **camber stiffness**. Modifying the above Whipple model with the tire force model results in the appearance of the wobble mode. Since lateral forces do not instantaneously respond to changes in slip angle and camber, the dynamic model,

$$\frac{\sigma}{v}\dot{F} + F = N(-k_\alpha \alpha + k_\phi \phi), \qquad (6)$$

is usually used where $\sigma > 0$ is called the **relaxation length** of the tire. This yields more realistic behavior (Sharp 1971). In this model the weave mode damping eventually decreases at higher speeds and the frequency does not continually increase. The frequency of the wobble mode is higher than that of the weave mode and its damping decreases at higher speeds.

Further Models

To obtain nonlinear models, resort is usually made to multi-body simulation codes. In recent years, several researchers have used such codes to make nonlinear models which take into account other features such as frame flexibility, rider models, and aerodynamics; see Cossalter (2006), Cossalter and Lot (2002), Sharp and Limebeer (2001), and Sharp et al. (2004). The nonlinear behavior of the tires is usually modeled with a version of the Magic formula; see Pacejka (2006), Sharp et al. (2004), and Cossalter et al. (2003). Another line of research is to use some of these models to obtain optimal trajectories for high performance; see Saccon et al. (2012).

Summary and Future Directions

We have presented a basic linearized model of a motorcycle or bicycle useful for the understanding and control of these two wheeled vehicles. It seems that inclusion of further features in the model and the consideration of full nonlinear behavior require the use of multibody simulation software. Future research will consider models which will include the engine, transmission, and an active pilot. Autonomous control of these vehicles will also be considered.

Synonyms

MHE

Abstract

Moving horizon estimation (MHE) is a state estimation method that is particularly useful for nonlinear or constrained dynamic systems for which few general methods with established properties are available. This entry explains the concept of full information estimation and introduces moving horizon estimation as a computable approximation of full information. The basic design

methods for ensuring stability of MHE are presented. The relationships of full information and MHE to other state estimation methods such as Kalman filtering and statistical sampling are discussed.

Keywords

Full information estimation; Kalman filtering; Statistical sampling

Introduction

In state estimation, we consider a dynamic system from which measurements are available. In discrete time, the system description is

$$x^+ = f(x, w) \qquad y = h(x) + v \qquad (1)$$

The state of the systems is $x \in \mathbb{R}^n$, the measurement is $y \in \mathbb{R}^P$, and the notation x^+ means x at the next sample time. A control input u may be included in the model, but it is considered a known variable, and its inclusion is irrelevant to state estimation, so we suppress it in the model under consideration here. We receive measurement y from the sensor, but the process disturbance, $w \in \mathbb{R}^g$; measurement disturbance $v \in \mathbb{R}^p$; and system initial state, $x(0)$, are considered unknown variables.

The goal of state estimation is to construct or estimate the trajectory of x from only the measurements y. Note that for control purposes, we are usually interested in the estimate of the state at the current time, T, rather than the entire trajectory over the time interval $[0, T]$. In the moving horizon estimation (MHE) method, we use optimization to achieve this goal. We have two sources of error: the state transition is affected by an unknown process disturbance (or noise), w, and the measurement process is affected by another disturbance, v. In the MHE approach, we formulate the optimization objective to minimize the size of these errors thus finding a trajectory of the state that comes close to satisfying the (error-free) model while still fitting the measurements.

First, we define some notation necessary to distinguish the system variables from the estimator variables. We have already introduced the system variables (x, w, y, v). In the estimator optimization problem, these have corresponding decision variables, which we denote by the Greek letters $(\chi, \omega, \eta, \nu)$. The relationships between these variables are

$$\chi^+ = f(\chi, \omega) \qquad y = h(\chi) + \nu \qquad (2)$$

and they are depicted in Fig. 1. Notice that ν measures the gap between the model prediction $\eta = h(\chi)$ and the measurement y. The *optimal* decision variables are denoted $(\hat{x}, \hat{w}, \hat{y}, \hat{v})$, and these optimal decisions are the estimates provided by the state estimator.

Full Information Estimation

The full information objective function is

$$V_T(\chi(0), \boldsymbol{\omega}) = \ell_x\big(\chi(0) - \overline{x}_0\big) + \sum_{i=0}^{T-1} \ell_i(\omega(i), \nu(i)) \tag{3}$$

subject to (2) in which T is the current time, $\boldsymbol{\omega}$ is the estimated sequence of process disturbances, $(\omega(0), \ldots, \omega(T-1))$, $y(i)$ is the measurement at time i, and $\overline{x}_0$ is the prior, i.e., available, value of the initial state. *Full information* here means that we use *all* the data on time interval $[0, T]$ to estimate the state (or state trajectory) at time T. The stage cost $\ell_i(\omega, \nu)$ costs the model disturbance and the fitting error, the two error sources that we reconcile in all state estimation problems.

The full information estimator is then defined as the solution to

$$\min_{\chi(0), \boldsymbol{\omega}} V_T(\chi(0), \boldsymbol{\omega}) \tag{4}$$

The solution to the optimization exists for all $T \in \mathbb{I}_{\geq 0}$ under mild continuity assumptions and choice of stage cost. Many choices of (positive, continuous) stage costs $\ell_x(\cdot)$ and $\ell_i(\cdot)$ are possible, providing a rich class of estimation problems
Moving Horizon Estimation, Fig. 1 The state, measured output, and disturbance variables appearing in the state estimation optimization problem. The state trajectory (*gray circles in lower half*) is to be reconstructed given the measurements (*black circles in upper half*)

that can be tailored to different applications. Because the system model (1) and cost function (3) are so general, it is perhaps best to start off by specializing them to see the connection to some classic results.

Related Problem: The Kalman Filter

If we specialize to the linear dynamic model $f(x, w) = Ax + Gw$, $h(x) = Cx$, and let $x(0)$, w, and v be independent, normally distributed *random* variables, the classic Kalman filter is known to be the statistically optimal estimator, i.e., the Kalman filter produces the state estimate that maximizes the conditional probability of $x(T)$ given $y(0), \ldots, y(T)$. The full information estimator is *equivalent* to the Kalman filter given the linear model assumption and the following choice quadratic of stage costs

$$\ell_x(\chi(0), \overline{x}_0) = (1/2) \|\chi(0) - \overline{x}_0\|_{P_0^{-1}}^2$$

$$\ell_i(\omega, v) = (1/2)\left(\|\omega\|_{Q^{-1}}^2 + \|v\|_{R^{-1}}^2 \right)$$

in which random variable $x(0)$ is assumed to have mean $\overline{x}_0$ and variance P_0 and random variables w and v are assumed zero mean with variances Q and R, respectively. The Kalman filter is also a *recursive* solution to the state estimation problem so that only the current mean $\hat{x}$ and variance P of the conditional density are required to be stored, instead of the entire history of measurements $y(i), i = 0, \ldots, T$. This computational efficiency is critical for success in online application for processes with short time scales requiring fast processing.

But if we consider nonlinear models, the maximization of conditional density is usually an intractable problem, especially in online applications. So, MHE becomes a natural alternative for nonlinear models or if an application calls for hard constraints to be imposed on the estimated variables.

Moving the Horizon

An obvious problem with solving the full information optimization problem is that the number of decision variables grows linearly with time T, which quickly renders the problem intractable for continuous processes that have no final time. A natural alternative to full information is to consider instead a finite moving horizon of the most recent N measurements. Figure 2 displays this idea. The initial condition $\chi(0)$ is now replaced by the initial state in the horizon, $\chi(T - N)$, and the decision variable sequence of process disturbances is now just the last N variables $\boldsymbol{\omega} = (\omega(T - N), \ldots, \omega(T - 1))$. Now, the big question remaining is what to do about the neglected, past data. This question is strongly related to what penalty to use on the initial state in the horizon $\chi(T - N)$. If we make this initial state a free variable, that is equivalent to completely discounting the past data. If we wish to retain some of the influence of the past data and keep the moving horizon estimation problem close to the full information problem, then we must choose an appropriate penalty for the initial state. We discuss this problem next.

Arrival Cost. When time is less than or equal to the horizon length, $T \leq N$, we can simply do full information estimation. So we assume throughout that $T > N$. For $T > N$, we express the MHE objective function as
Moving Horizon Estimation, Fig. 2 Schematic of the moving horizon estimation problem

$$\hat{V}_T(\chi(T - N), \boldsymbol{\omega}) = \Gamma_{T-N}(\chi(T - N))$$
$$+ \sum_{i=T-N}^{T-1} \ell_i(\omega(i), v(i))$$

subject to (2). The MHE problem is defined to be

$$\min_{\chi(T-N), \boldsymbol{\omega}} \hat{V}_T(\chi(T - N), \boldsymbol{\omega}) \qquad (5)$$

in which $\boldsymbol{\omega} = \{\omega(T - N), \ldots, \omega(T - 1)\}$ and the hat on V distinguishes the MHE objective function from full information. The designer must now choose this prior weighting $\Gamma_k(\cdot)$ for $k > N$.

To think about how to choose this prior weighting, it is helpful to first think about solving the full information problem by breaking it into *two* non-overlapping sequences of decision variables: the decision variables in the time interval corresponding to the neglected data $(\omega(0), \omega(1), \ldots, \omega(T - N - 1))$ and those in the time interval corresponding to the considered data in the horizon $(\omega(T - N), \ldots, \omega(T - 1))$. If we optimize over the first sequence of variables and store the solution as a function of the terminal state $\chi(T - N)$, we have defined what is known as the arrival cost. This is the optimal cost to arrive at a given state value.

Definition 1 (arrival cost) The (full information) arrival cost is defined for $k \geq 1$ as

$$Z_k(x) = \min_{\chi(0), \boldsymbol{\omega}} V_k(\chi(0), \boldsymbol{\omega}) \qquad (6)$$

subject to (2) and $\chi(k; \chi(0), \boldsymbol{\omega}) = x$.

Notice the terminal constraint that χ at time k ends at value x. Given this arrival cost function, we can then solve the full information problem by optimizing over the remaining decision variables. What we have described is simply the *dynamic programming* strategy for optimizing over a sum of stage costs with a dynamic model (Bertsekas 1995).

We have the following important equivalence.

Lemma 1 (MHE and full information estimation) *The MHE problem* (5) *is equivalent to*

the full information problem (4) *for the choice* $\Gamma_k(\cdot) = Z_k(\cdot)$ *for all* $k > N$ *and* $N \geq 1$.

Using dynamic programming to decompose the full information problem into an MHE problem with an arrival cost penalty is conceptually important to understand the structure of the problem, but it doesn't yet provide us with an implementable estimation strategy because we cannot compute and store the arrival cost when the model is nonlinear or other constraints are present in the problem. But if we are not too worried about the optimality of the estimator and are mainly interested in other properties, such as stability of the estimator, we can find simpler design methods for choosing the weighting $\Gamma_k(\cdot)$. We address this issue next.

Estimator Properties: Stability

An estimator is termed *stable* if small disturbances (w, v) lead to small estimate errors $x - \hat{x}$ as time increases. Precise definitions of this basic idea are available elsewhere (Rawlings and Ji 2012), but this basic notion is sufficient for the purposes of this overview. In applications, properties such as stability and insensitivity to model errors are usually more important than optimality. It is possible for a filter to be *optimal* and still not *stable*. In the linear system context, this cannot happen for "nice" systems. Such nice systems are classified as *detectable*. Again, the precise definition of detectability for the linear case is available in standard references (Kwakernaak and Sivan 1972). Defining detectability for nonlinear systems is a more delicate affair, but useful definitions are becoming available for the nonlinear case as well (Sontag and Wang 1997).

If we lower our sights and do not worry if MHE is equivalent to full information estimation and require only that it be a stable estimator, then the key result is that the prior penalty $\Gamma_k(\cdot)$ need only be chosen *smaller* than the arrival cost as shown in Fig. 3. See Rawlings and Mayne (2009, Theorem 4.20) for a precise statement of this result. Of course this condition includes the flat arrival cost, which does not penalize the initial
Moving Horizon Estimation, Fig. 3 Arrival cost $Z_k(x)$, underbounding prior weighting $\Gamma_k(x)$, and MHE optimal value $\hat{V}_k^0$; for all x and $k > N$, $Z_k(x) \geq \Gamma_k(x) \geq \hat{V}_k^0$, and $Z_k(\hat{x}(k)) = \Gamma_k(\hat{x}(k)) = \hat{V}_k^0$

state in the horizon at all. So neglecting the past data completely leads to a stable estimator for detectable systems. If we want to improve on this performance, we can increase the prior penalty, and we are guaranteed to remain stable as long as we stay below the upper limit set by the arrival cost.

Related Problem: Statistical Sampling

MHE is based on optimizing an objective function that bears some relationship to the conditional probability of the state (trajectory) given the measurements. As discussed in the section on the Kalman filter, if the system is linear with normally distributed noise, this relationship can be made exact, and MHE is therefore an optimal statistical estimator. But in the nonlinear case, the objective function is chosen with engineering judgment and is only a surrogate for the conditional probability. By contrast, sampling methods such as particle filtering are designed to sample the conditional density also in the nonlinear case. The mean and variance of the samples then provide estimates of the mean and variance of the conditional density of interest. In the limit of infinitely many samples, these methods are exact. The efficiency of the sampling methods depends strongly on the model and the dimension

of the state vector n, however. The efficiency of the sampling strategy is particularly important for online use of state estimators. Rawlings and Bakshi (2006) and Rawlings and Mayne (2009, pp. 329–355) provide some comparisons of particle filtering with MHE and also describe some hybrid methods combining MHE and particle filtering.

Summary and Future Directions

MHE is one of few state estimation methods that can be applied to nonlinear models for which properties such as estimator stability can be established (Rao et al. 2003; Rawlings and Mayne 2009). The required online solution of an optimization problem is computationally demanding in some applications but can provide significant benefits in estimator accuracy and rate of convergence (Patwardhan et al. 2012). Current topics for MHE theoretical research include treating bounded rather than convergent disturbances and establishing properties of suboptimal MHE (Rawlings and Ji 2012). The current main focus for MHE applied research involves reducing the online computational complexity to reliably handle challenging large dimensional, nonlinear applications (Kuhl et al. 2011; Lopez-Negrete and Biegler 2012; Zavala and Biegler 2009; Zavala et al. 2008).

Abstract

One starting point for the analysis and design of a control system is the block diagram representation of a plant. Since it is nontrivial to convert a physical model of a plant into a block diagram, this can be performed manually only for small plant models. Based on research from the last 35 years, more and more mature tools are available to achieve this transformation fully automatically. As a result, multi-domain plants, for example, systems with electrical, mechanical, thermal, and fluid parts, can be modeled in a unified way and can be used directly as input–output blocks for control system design. An overview of the basic principles of this approach is given. This provides also the possibility to use nonlinear, multi-domain plant models directly in a controller. Finally, the low-level "Functional Mockup Interface" standard is sketched to exchange multi-domain models between many different modeling and simulation environments.

Keywords

Introduction

Methods and tools for control system analysis and design usually require an input–output block diagram description of the plant to be controlled. Apart from small systems, it is nontrivial to derive such models from first principles of physics. Since a long time, methods and tools are available to construct such models automatically for one domain, for example, a mechanical model, an electronic, or a hydraulic circuit. These domain-specific methods and tools are, however, only of limited use for the modeling of multi-domain systems.

In the dissertation (Elmqvist 1978), a suitable approach for multi-domain, object-oriented modeling has been developed by introducing a modeling language to define models on a high level based on first principles. The resulting DAE (differential-algebraic equation) systems are transformed with proper algorithms automatically in a block diagram description with input and output signals based on ODEs (ordinary differential equations).

In 1978, the computers were not powerful enough to apply this method on larger systems. This changed in the 1990s, and then the technology has been substantially improved, many different modeling languages appeared (and also disappeared), and the technology was introduced in commercial simulation environments.

In Table 1, an overview of the most important standards, languages, and tools in the year 2013 for multi-domain modeling is given:

The Modelica language is a standard from The Modelica Association (Modelica Association 2012). The first version was released in 1997. Also a large free library is provided with about 1,300 model components from many domains. There are several software tools supporting this modeling language and the free Modelica

- The VHDL-AMS language is a standard from IEEE (IEEE 1076.1-2007 2007), first released in 1999. It is an extension of the widely used VHDL hardware description language. This language is especially used in the electronics community.

- There are several vendor-specific modeling languages, notably Simscape from Math-Works as an extension to Simulink, as well as MAST, the underlying modeling language of Saber (Mantoolh and Vlach 1992). In 2004, MAST was published as OpenMAST under an open source license.

- Bond graphs (see, e.g., Karnopp et al. 2012) are a special graphical notation to define multi-domain systems based on energy flow. It was invented in 1959 by Henry M. Paynter.

In the section "Modeling Language Principles", the principles of multi-domain modeling based on a modeling language are summarized. In the section "Models for Control Systems", it is shown how such models can be used not only for simulation but also as components in nonlinear control systems. Finally, in the section

"The Functional Mockup Interface", an overview about a low-level standard for the exchange of multi-domain systems is described.

Modeling Language Principles

Schematics: The Graphical View

Modelers nowadays require a simple to use graphical environment to build up models. With very few exceptions, multi-domain environments define models by schematic diagrams. A typical example is given in Fig. 1, showing a simple direct-current electrical motor in Modelica.

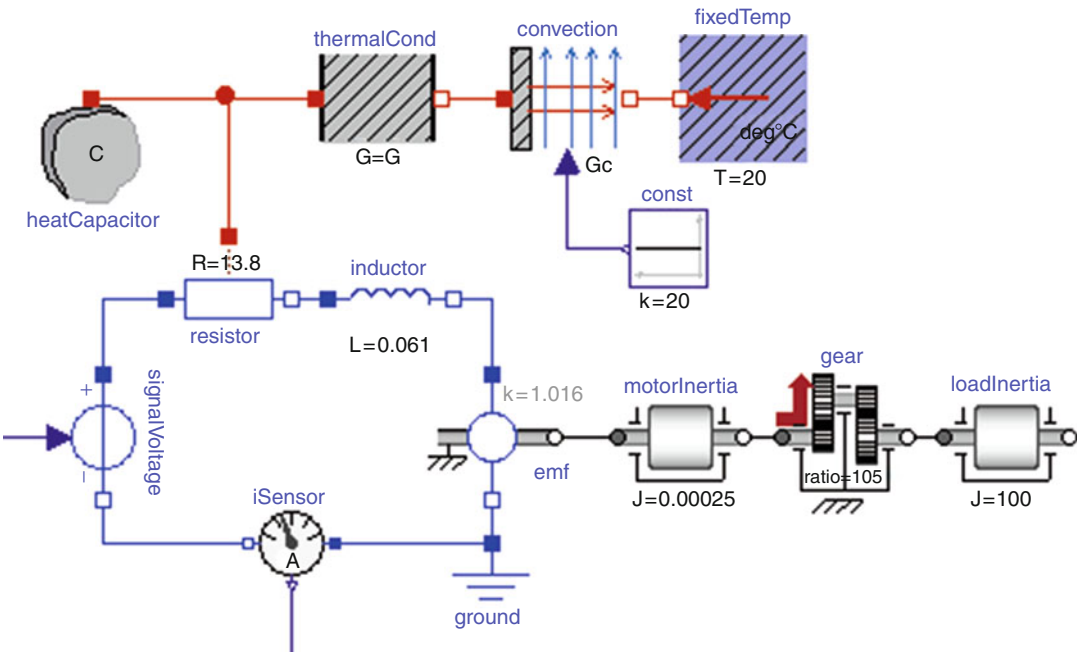
In the lower left part, the electrical circuit diagram of the DC motor is visible, consisting mainly of the armature resistance and inductance of the motor, a voltage source, and component "emf" to model in an idealized way the electromotoric forces in the air gap. On the lower right part, the motor inertia, a gear box, and a load inertia are present. In the upper part, the heat transfer of the resistor losses to the environment is modeled with lumped elements.

A component, like a resistor, rotational inertia, or convective heat transfer, is shown as an icon in the diagram. On the border of a component, small rectangular or circular signs are present representing the "physical ports." Ports are connected by lines and model the (idealized) physical or signal interaction between ports of different components, for example, the flow of electrical current or heat or the rigid mechanical coupling.

Components are built up hierarchically from other components. On the lowest level, components are described textually with the respective modeling language (see section "Component Equations").

Coupling Components by Ports

The ports define how of a component can interact with other components. A port contains (a) a definition of the variables that describe the interface and (b) defines in which way a tool can automatically construct the equations of connections. A typical scenario is shown in Fig. 2 where the ports of the three components A, B, C are connected together at one point P:

M


Multi-domain Modeling and Simulation, Fig. 1 Modelica schematic of DC motor with mechanical load and heat losses

When cutting away the connection lines, the resulting system consists of three decoupled components A, B, C and a new component around P describing the infinitesimally small connection point. The balance equations and the boundary conditions of the respective domain must hold at all these components. When drawing the connection lines, enough information must be available in the port definitions so that the tool can construct the equations of the infinitesimally small connection points automatically.

To summarize, the component developer is responsible that the balance equations and boundary conditions are fulfilled for every component (A, B, C in Fig. 2), and the tool is responsible that the balance equations and boundary conditions are also fulfilled at the points where the components are connected together (P in Fig. 2). As a
consequence, the balance equations and boundary conditions are fulfilled in the overall model containing all components and all connections.

In order that a tool can automatically construct the equations at a connection point, every port variable needs to be associated to a port variable type. In Table 2, some port variable types of Modelica are shown. In this table it is assumed that $u_1, u_2, \ldots u_n, y, v_1, v_2, \ldots, v_n, f_1, f_2, \ldots, f_n, s_1, s_2, \ldots, s_n$ are corresponding port variables from different components that are connected together at the same point P.

Port variable types "input" and "output" define the "usual" signal connections in block diagrams.

"Potential variables" and "flow variables" are used to define standard physical connections. For example, an electrical port contains the electrical potential and the electrical current at the port, and when connecting electrical ports together, the electrical potentials are identical and the sum of the electrical currents is zero, according to Table 2. This corresponds exactly to Kirchhoff's voltage and current laws.

"Stream variables" are used to describe the connection semantics of intensive quantities in bidirectional fluid flow, such as specific enthalpy or mass fraction. Here, the idealized balance equation at a connection point states, for example, that the sum of the port enthalpy flow rates is zero and the port enthalpy flow rate is computed as the product of the mass flow rate (a flow variable f_i) and the directional specific enthalpy s_i, which is either the (yet unknown) mixing-specific enthalpy s_{mix} when the flow is from the connection point to the port or the specific enthalpy s_i in the port when the flow is from the port to the connection point. More details

Multi-domain Modeling and Simulation, Fig. 2 Cutting the connections around the connection point P results in three decoupled components *A*, *B*, *C* and a new component around *P* describing the infinitesimally small connection point

Multi-domain Modeling and Simulation, Table 2 Some port variable types in Modelica

Port variable type	Connection semantics
Input variables u_i, output variable y	$u_1 = u_2 = \ldots = u_n = y$ (exactly one output variable can be connected to n input variables)
Potential variables v_i	$v_1 = v_2 = \ldots = v_n$
Flow variables f_i	$0 = \sum f_i$
Stream variables s_i (with associated flow variables f_i)	$0 = \sum f_i \hat{s}_i;\ \hat{s}_i = \begin{cases} s_{mix} & \text{if } f_i > 0 \\ s_i & \text{if } f_i \leq 0 \end{cases}$ $(0 = \sum f_i)$

and explanations are available from Franke et al. (2009). In Table 3 some of the port definitions are shown that are defined in the Modelica Standard Library.

Component Equations

Implementing a component in a modeling language means to (a) define the ports of the component and (b) provide the equations describing the relationships between the port variables. For example, an electrical capacitor with constant capacitance C can be defined by the equations in the right side of Fig. 3.

Such a component has two ports, the pins "p" and "n," and the port variables are the electrical currents i_p, i_n flowing into the respective ports and the electrical potentials v_p, v_n at the ports. The first component equation states that if the current i_p at port "p" is positive, then the current i_n at port "n" is negative (therefore, the current flowing into "p" is flowing out of "n").

$$0 = i_p + i_n$$
$$u = v_p - v_n$$
$$C\frac{du}{dt} = i_p$$

Multi-domain Modeling and Simulation, Fig. 3 Equations of a capacitor component

Furthermore, the two remaining equations state that the derivative of the difference of the port potentials is proportional to the current flowing into port "p."

One important question is how many equations are needed to describe such a component? For an input–output block, this is simple: all input variables are known, and for all other variables, one equation per unknown is needed. Counting equations for physical components, such as a capacitor, is more involved: the requirement

that any type of component connections shall always result in identical numbers of unknowns and equations of the overall system leads to the following counting rule (for a proof, see Olsson et al. 2008):

1. The number of potential and the number of flow variables in a port must be identical.
2. Input variables and variables that appear differentiated are treated as known variables.
3. The number of equations of a component must be equal to the number of unknowns minus the number of flow variables.

In the example of the capacitor, there are 5 unknowns (i_p, i_n, v_p, v_n, du/dt) and **2** flow variables (i_p, i_n). Therefore, $5 - 2 = 3$ equations are needed to define this component.

Modeling languages are used to provide a textual description of the ports and of the equations in a specific syntax. For example, in Modelica the capacitor from Fig. 3 can be defined as Fig. 4 (keywords of the Modelica language are written in boldface):

In VHDL-AMS the capacitor model can be defined as shown in Fig. 5.

One difference between Modelica and VHDL-AMS is that in Modelica all equations need to be explicitly given and port variables (such as p.i) can be directly accessed in the model (Fig. 4). In-stead, in VHDL-AMS (and some other modeling languages), port variables cannot be accessed in a model, and instead via the "**quantity** .. **across** .. **through** .. **to** .." construction, the relationships between the port variables are implicitly defined and correspond to the Modelica equations "0 = p.i + n.i" and "u = p.v − n. v."

Simulation of Multi-domain Systems

Collecting all the component equations of a multi-domain system model together with all connection equations results in a DAE (differential-algebraic equation) system:

$$0 = \mathbf{f}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{w}, \mathbf{y}, \mathbf{u}, t) \tag{1}$$

where $t \in \mathbb{R}$ is time, $\mathbf{x}(t) \in \mathbb{R}^{n_x}$ are variables appearing differentiated, $\mathbf{w}(t) \in \mathbb{R}^{n_w}$ are algebraic variables, $\mathbf{y}(t) \in \mathbb{R}^{n_y}$ are outputs, $\mathbf{u}(t) \in \mathbb{R}^{n_u}$ are inputs, and $\mathbf{f} \in \mathbb{R}^{n_x+n_w+n_y}$ are the DAE equations. Equation (1) can be solved numerically with an integrator for DAE systems; see, for example, Brenan et al. (1996). For DAEs that are linear in their unknowns, a complete theory for solvability is available based on *matrix pencils* (see, e.g., Brenan et al. 1996) and also reliable software for their analysis (Varga 2000).

Unfortunately, only certain classes of *nonlinear* DAEs can be *directly* solved numerically

in a reliable way. Domain-specific software, as, e.g., for mechanical systems, transforms the underlying DAE into a form that can be more reliably solved, using domain-specific knowledge. This is performed by differentiating certain equations of the DAE analytically and utilizing special integration methods for the resulting overdetermined set of differential-algebraic equations. Multi-domain simulation software uses the following approaches:

(a) The DAE (1) is directly solved numerically using an implicit integration method, such as a linear multistep method. Typically, all VHDL-AMS simulators use this approach.

(b) The DAE (1) is symbolically transformed in a form that is equivalent to a set of ODEs (ordinary differential equations), and then either explicit or implicit ODE or DAE integration methods are used to numerically solve the transformed system. The transformation is based on the algorithms of Pantelides (1988) and of Mattsson and Söderlind (1993) and might require to analytically differentiate equations. Typically, all Modelica-based simulators, but also EcosimPro, use this approach.

For many models both approaches can be applied successfully. There are, however, systems where approach (a) is successful and fails for (b) or vice versa.

DAEs (1) derived from modeling languages usually have a large number of equations but with only a few unknowns in every equation. In order to solve DAEs of this kind efficiently, both with (a) or (b), typically graph theory and/or sparse matrix methods are utilized. For method (b) the fundamental algorithms have been developed in Elmqvist (1978) and later improved in further publications. For a recent survey and comparison of some of the algorithms, see Frenkel et al. (2012).

Solving the DAE (1) means to solve an initial value problem. In order that this can be performed, a consistent set of initial variables $\dot{\mathbf{x}}_0 = \dot{\mathbf{x}}(t_0)$, $\mathbf{x}_0 = \mathbf{x}(t_0)$, $\mathbf{w}_0 = \mathbf{w}(t_0)$, $\mathbf{y}_0 = \mathbf{y}(t_0)$, $\mathbf{u}_0 = \mathbf{u}(t_0)$ has to be determined first at the initial time t_0. In general, this is a nontrivial task. For example, often (1) shall start in steady state, that is, it is required that $\dot{\mathbf{x}}_0 = 0$ and therefore at the initial time (1) is required to satisfy

$$0 = \mathbf{f}(0, \mathbf{x}_0, \mathbf{w}_0, \mathbf{y}_0, \mathbf{u}_0, t_0) \qquad (2)$$

Equation (2) is a nonlinear algebraic system of equations in the unknowns $\mathbf{x}_0, \mathbf{w}_0, \mathbf{y}_0, \mathbf{u}_0$. These are $n_x + n_w + n_y$ equations for $n_x + n_w + n_y + n_u$ unknowns. Therefore, n_u further conditions must be provided (usually some elements of $\mathbf{u}_0$ and/or $\mathbf{y}_0$ are fixed to desired physical values). Solving (2) for the unknowns is also called "DC operating point calculation" or "trimming." Nonlinear equation solvers are based on iterative methods that require usually a sufficiently accurate initial guess for all unknowns. In a large multi-domain system model, this is not practical, and therefore, methods are needed to solve (2) even if generic guess values in a library are provided that might be far from the solution of the system at hand.

For analog electronic circuit simulations, a large body of theory, algorithms, and software is available to solve (2) based on homotopy methods. The basic idea is to solve a sequence of nonlinear algebraic equation systems by starting with an easy to solve simplified system, characterized by the homotopy parameter $\lambda = 0$. This system is continuously "deformed" until the desired one is reached at $\lambda = 1$. The solution at iteration i is used as guess value for iteration $i + 1$, and at every iteration, the solution is usually computed with a Newton-Raphson method.

The simplest such approach is "source stepping": the initial guess values of all electrical components are set to "zero voltage" and/or "zero current." All (voltage and current) sources start at zero, and their values are gradually increased until the desired source values are reached. This method may not converge, typically due to the severe nonlinearities at switching thresholds in logical circuits.

There are several, more involved approaches, called "probability one homotopy" methods. For these method classes, proofs exist that they converge with probability one (so practically always). These algorithms can only be applied for certain classes of DAEs; see, for example, the

"Variable Stimulus Probability One Homotopy" from Melville et al. (1993).

Although strong results exist for analog electrical circuit simulators, it is difficult to generalize them to the large class of multi-domain systems covered by a modeling language. In Modelica a "homotopy" operator was introduced into the language (Sielemann et al. 2011) in order that a library developer can formulate simple homotopy methods like the "source stepping" in a component library. A generalization of probability one methods for multi-domain systems was developed in the dissertation of Sielemann (2012) and was successfully applied to air distribution systems described as 1-dim. thermo-fluid pipe flow.

Models for Control Systems

Models for Analysis

The multi-domain models from section "Modeling Language Principles" can be utilized to evaluate the properties of a control system by simulation. Also control systems can be designed by nonlinear optimization where at every optimization step one or several simulations of a plant model are executed. Furthermore, modeling environments usually provide a means to linearize the nonlinear DAE (1) of the underlying model around an operating point:

$$\mathbf{x}(t) \approx \mathbf{x}_{op} + \Delta\mathbf{x}(t), \mathbf{w}(t) \approx \mathbf{w}_{op} + \Delta\mathbf{w}(t),$$
$$\mathbf{y}(t) \approx \mathbf{y}_{op} + \Delta\mathbf{y}(t), \ \mathbf{u}(t) \approx \mathbf{u}_{op} + \Delta\mathbf{u}(t)$$
(3)

resulting in

$$\Delta\dot{\mathbf{x}}_{red} = \mathbf{A}\,\Delta\mathbf{x}_{red} + \mathbf{B}\,\Delta\mathbf{u}$$
$$\Delta\mathbf{y} = \mathbf{C}\,\Delta\mathbf{x}_{red} + \mathbf{D}\,\Delta\mathbf{u}$$
(4)

where $\Delta\mathbf{x}_{red}$ is a vector consisting of elements of the vector of $\Delta\mathbf{x}$, the vector $\Delta\mathbf{w}$ is eliminated by exploiting the algebraic constraints, and $\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathbf{D}$ are constant matrices. Simulation tools provide linear analysis and synthesis methods on this linearized system and/or export it for usage in an environment like Matlab, Maple, Mathematica, or Python.

Multi-domain models might also be used directly in nonlinear Kalman filters, moving horizon estimators, or nonlinear model predictive control. For example, the company ABB is using moving horizon estimation and nonlinear model predictive control based on Modelica models to significantly improve the start-up process of power plants (Franke and Doppelhamer 2006).

Inverse Models

A large body of literature exists about the theory of nonlinear control systems that are based on *inverse* plant models; see, for example, Isidori (1995). Methods such as feedback linearization, nonlinear dynamic inversion, or flat systems use an inverse plant model in the control loop. However, a major obstacle is how to *automatically* utilize an inverse plant model in a controller without being forced to manually set up the equations in the needed form which is not practical for larger systems. Modeling languages can solve this problem as discussed below.

Nonlinear inverse models can be utilized in various ways in a control system. The simplest approach, as feed forward controller, is shown in Fig. 6.

Under the assumption that the models of the plant and of the inverse plant are completely identical and start at the same initial state, then from the construction the control error $\mathbf{e}$ is zero and $\mathbf{y} = \mathbf{T}(s) * \mathbf{y}_{ref}$ where $\mathbf{T}$ is a diagonal matrix with the transfer functions of the low-pass filters on the diagonal (so $\mathbf{y} \approx \mathbf{y}_{ref}$ for reference signals
Multi-domain Modeling and Simulation, Fig. 6 Controller with inverse plant model in the feed forward path. The inverse plant model needs usually also derivatives of $\mathbf{y}_{ref}$ as inputs. These derivatives are provided by appropriate low-pass filters

that have a frequency spectrum below the cutoff frequency of the low-pass filters). Since actually the assumption is usually not fulfilled, there will be a nonzero control error **e** and the feedback controller has to cope with it. This controller structure with a nonlinear inverse plant model has the advantage that the feed forward part is useful over the complete operating range of the plant.

Various other structures with nonlinear plant models are discussed in Looye et al. (2005), such as compensation controllers, feedback linearization controllers, and nonlinear disturbance observers.

It turns out that nonlinear inverse plant models can be generated automatically with the techniques that have been developed for modeling languages; see section "Modeling Language Principles". In particular, constructing an inverse model from (1) means that the inputs u are defined to be outputs, so they are no longer knowns but unknowns, and outputs y are defined to be inputs, so they are no longer unknowns but knowns. The resulting system is still a DAE and can therefore be handled as any other DAE.

Therefore, defining an inverse model with a modeling language just requires exchanging the definition of input and output signals. In Modelica, this can be graphically performed with the nonstandard input–output block from Fig. 8.

This block has two inputs and two outputs and described by the equations

$$u1 = u2; \quad y1 = y2$$

From a block diagram point of view this looks strange. However, from a DAE point of view, this just states constraints between two input and two output signals. In Fig. 8, it is shown how this block can be used to invert a simple second order system.

The output of the low-pass filter is connected to the output of the second-order system and therefore this model computes the input of the second-order system, from the input of the filter.

A Modelica environment will generate from this type of definition the inverse model, thereby differentiating equations analytically and solving algebraic variables of the model in a different way as for a simulation model. The whole transformation is nontrivial, but it is just the standard method used by Modelica tools as for any other type of DAE system.

The question arises whether a solution of the inverse model exists, is unique, and whether the model is stable (otherwise, it cannot be applied in a control system). In general, a nonlinear inverse model consists of linear and/or nonlinear algebraic equation systems and of linear and/or nonlinear differential equations. Therefore, from a formal point of view, the same theorems as for a general DAE apply; see, for example, Brenan et al. (1996). Furthermore, all these equations need to be solved with a numerical method. For some classes of systems, it can be shown that mathematically a unique solution exists and that the system is stable. However, in general, one cannot expect that it is possible to provide such a proof for complex inverse plant models. Still, inverse plant models have been successfully utilized by automatic generation from a Modelica tool, e.g., for robots, satellites, aircrafts, vehicles, and thermo-fluid systems.

The Functional Mockup Interface

Many different types of simulation environments are in use. One cannot expect that a generic approach as sketched in section "Modeling Language Principles" will replace all these environments with their rich set of domain-specific knowledge, analysis, and synthesis features. Practically, all simulation environments provide a vendor-specific interface in order that a user can import components that are not describable by the simulation environment itself. Typically, this requires to provide a component as a set of C or Fortran functions with a particular calling interface. In the control community, the most widely used approach of this kind is the S-Function interface from The MathWorks, where Simulink is used as integration platform, and model components from other environments are imported as S-Functions.
Multi-domain Modeling and Simulation, Fig. 7 Modelica InverseBlockConstraint block
Multi-domain Modeling and Simulation, Fig. 8 Inversion of a second-order system in Modelica

In 2010 the vendor-independent standard "Functional Mockup Interface 1.0" was published (FMI Group 2010). This is a low-level standard for the exchange of models between different simulation environments. This standard allows to exchange only either the model equations (called "FMI for Model Exchange") or the model equations with an embedded solver (called "FMI for Co-Simulation"). This standard was quickly adopted by many simulation environments, and in 2013 there are more than 40 tools that support it (for an actual list of tools, see https://www.fmi-standard.org/tools). In particular nearly all Modelica environments can export Modelica models in this format, and therefore, Modelica multi-domain models can be imported in other environments with low effort.

A software component which implements the FMI is called Functional Mockup Unit (FMU). An FMU consists of one zip-file with extension ".fmu" containing all necessary components to utilize the FMU either for Model Exchange, for Co-Simulation, or for both. The following summary is an adapted version from Blochwitz et al. (2012):

1. An *XML-file* contains the definition of all exposed variables of the FMU, as well as other model information. It is then possible to run the FMU on a target system without this information, i.e., without unnecessary overhead. Furthermore, this allows determining all properties of an FMU from a text file, without actually loading and running the FMU.

2. A set of *C-functions* is provided to execute model equations for the Model Exchange case and to simulate the equations for the Co-Simulation case. These C-functions can be provided either in binary form for different platforms or in source code. The different forms can be included in the same model zip-file.

3. Further data can be included in the FMU zip-file, especially a model icon (bitmap file), documentation files, maps and tables needed by the model, and/or all object libraries or DLLs that are utilized.

Summary and Future Directions

Multi-domain modeling based on a DAE description and defined with a modeling language is an established approach, and many tools support it. This allows to conveniently define plant models from many domains for the design and evaluation of control systems. Furthermore, nonlinear inverse plant models can be easily constructed with the same methodology and can be utilized in various ways in nonlinear control systems.

Current research focuses on the support of the complete life cycle: defining requirements of a system formally on a "high level,"

considerably improving testing by checking these requirements automatically when evaluating a system design by simulations, and providing complete tool chains from nonlinear multi-domain models to embedded systems. The latter will allow convenient and fast target code generation of nonlinear controllers, extended and unscented Kalman filters, optimization-based controllers, or moving horizon estimators.

Furthermore, the methodology itself is further improved. For example, in 2012, Modelica was extended with language elements to define multi-rate sampled data systems in a precise way, as well as state machines.

Multiscale Multivariate Statistical Process Control

Julian Morris
School of Chemical Engineering and Advanced Materials, Centre for Process Analytics and Control Technology, Newcastle University, Newcastle Upon Tyne, UK

Synonyms

MSPCA

Abstract

Dynamic processes, both continuous and batch, are characterised by autocorrelated measurements which are allied to the effects of process dynamics and disturbances. The common multivariate statistical process control (MSPC) approaches have been to use principal component analysis (PCA) or projection to latent structures (PLS) to build a model that captures the simultaneous correlations amongst the variables, but that ignores the serial correlation in the data during normal operations. Under such conditions it is difficult to perform efficient fault detection and diagnosis. An alternative approach to account for the process dynamics in MSPC is to use multiresolution analysis (MRA) by way of wavelet decomposition. Here, the individual measurements are decomposed into different

scales (or frequencies) and the signals in each decomposed scale are then used for MSP which provides an indirect way of handling process dynamics.

Keywords

Multiresolution analysis; Partial least squares (PLS); Principal component analysis (PCA); Projection to latent structures (PLS); Wavelet transform

Definition

Multiscale principal component analysis (MSPCA) and its extension multiscale projection to latent structures (MSPLS) combine the abilities of these multivariate tools to decorrelate the variables by extracting linear relationships with that of wavelet analysis, to extract deterministic features and approximately de-correlate autocorrelated measurements. Multiscale modeling makes use of the wavelet transform which allows a signal (measurement) to be viewed in multiple resolutions with each resolution representing a different frequency. That is, wavelet transform allows complex information to be decomposed into basic components at different positions and scales.

Motivation and Background

One of the drawbacks of the conventional PCA (or PLS)-based MSPC is that although the PCA/PLS model captures the correlations among the variables, it ignores the serial (auto)correlation in the process variables and measurements. One way to overcome this issue is to include time-lagged variables in the PCA or PLS model. In this way, PCA and PLS will explicitly model both the correlations among the variables and the serial correlations in the individual variables. The impact is an increase in the number principal components required, but the multivariate monitoring model will be able to detect any changes in the serial correlation of

the variables as well as changes in relationships among the variables. This article focuses on multiscale-multiway PCA using batchwise data unfolding. However, the methodology can equally be applied to PLS-based process performance monitoring (MSPC).

In multivariate statistical process control (MSPC), the multivariate statistical techniques of principle component analysis (PCA) and projection to latent structures {Partial Least Squares} (PLS) together with monitoring metrics based on Hotelling's T^2 (directly related to the Mahalanobis distance that monitors the fit of new observations to the model space) and the squared prediction error (SPE) or Q statistic (that monitors the residual space-model mismatch) are used to simultaneously monitor the process variables (Kourti and MacGregor 1996; Qin 2003). A recent survey provides an excellent state-of-the-art review of the methods and applications of data-driven fault detection and diagnosis that have been developed over the last two decades (Qin 2012).

Process measurements typically exhibit multi-scale behavior as a consequence of representing the cumulative effect of a number of underlying process phenomena including process dynamics, measurement noise, and disturbances. To address these issues, methodologies are required to address (i) the multiscale nature of process data and (ii) the inability of some existing algorithms to handle autocorrelation. One approach is through the use of multiresolution analysis and wavelets Mallat (1998). Informative discussions and application studies related to using multiresolution analysis and wavelet decompositions to enhance PCA-based process monitoring and fault detection have been presented, for example, by Bakshi (1998), Misra et al. (2002), Aradhye et al. (2003), Lu et al. (2003), Yoon and MacGregor (2004) and Reis and Saraiva (2006). Yoon and MacGregor in their comprehensive MSPCA study discussed their approach in the context of other multiscale approaches and illustrated the methodology using simulated data from a continuous stirred-tank reactor system. A major contribution of the paper was to extend fault isolation methods based on contribution plots to multiscale PCA approaches. Although some 9 years old, Ganesan et al. (2004)

provided review of wavelet-based multiscale statistical process monitoring.

The Approach

Multiresolution analysis (MRA) provides the theoretical basis for the derivation of a computationally efficient algorithm for the wavelet transform Mallat (1998). MRA allows the dynamic aspects of the data in to be taken into account in MSPC. The individual signals are decomposed into different scales (frequencies), and data in each decomposed scale are then used for MSPC which provides an indirect approach to handling process dynamics. Multiscale MSPC (MSPCA) enables the simultaneous extraction of process correlations across data as well as accounting for autocorrelation within sensor data. In this way, it captures correlations among the process variables made by various events occurring at different scales.

MSPCA calculates the principal components of wavelet coefficients at each scale and combines these at the relevant wavelet scales. Due to its multiscale nature, MSPCA is very useful for the modeling of data containing contributions from events whose behavior changes over both time and frequency. Process monitoring by MSPCA, and process prediction by MSPLS, involves combining those scales where significant events are detected. Approximate de-correlation of wavelet coefficients also makes MSPCA effective for the monitoring of autocorrelated measurements.

The Algorithm

Wavelets are a family of basis functions that provide a mapping from the time domain to the time-frequency domain. They can be used to decompose the signal into different resolutions by projecting onto the corresponding wavelet basis functions using multiresolution analysis (MRA). A wavelet set is constructed from a fundamental basis function or the mother wavelet by a process of translation and dilation. The wavelet set is defined as wavelet analysis which provides

methodologies for the extraction of the time and frequency content of a signal. Conventional frequency analysis based on the Fourier transform consists of decomposing a signal into sine waves of different frequencies. Wavelet analysis decomposes the original signal in a similar manner. The major difference is that while Fourier analysis uses sine waves of infinite length, multiresolution analysis uses waveforms of finite length. The finite length of the wavelets allows them to describe local events in both the time and frequency domain.

The wavelet transform, an extension to the Fourier transform, projects the original signal down onto wavelet basis functions, providing a mapping from the time domain to the timescale plane. The wavelet functions, which are localized in the time and frequency domain, are obtained from a single prototype wavelet, the *mother wavelet*, by dilation and translation. The wavelet set is defined as

$$\psi_{a,b}(t) = \frac{1}{\sqrt{|a|}} \psi \left(\frac{t-b}{a} \right)$$

where ψ is the mother wavelet function, a the dilation parameter, and b the translation parameters, and the factor $\frac{1}{\sqrt{|a|}}$ is used to ensure that each wavelet function has the same energy as the mother wavelet. The discrete wavelet transform with dyadic dilation and translation is used in this overview. A definition of continuous and discrete wavelet transforms can be found in Daubechies (1992). In the discrete case, the dilation and translation parameters are discretized as $a = a_0^m$ and $b = kb_0 a_0^m$. If $a_0 = 2$ and $b_0 = 1$, a *dyadic* dilation and translation is carried out; however, a_0 and b_0 are not restricted to these values. The discrete wavelet form, which is widely used in process monitoring and chemical signal analysis, is

$$\psi_{jk}(t) = a_0^{-j/2} \psi(a_0^{-j_t} - kb_0)$$

A recursive algorithm for wavelet decomposition and the reconstruction of a discrete signal of dyadic length is often used Mallat (1998) and is known as the pyramid algorithm. The fast discrete wavelet decomposition consists of

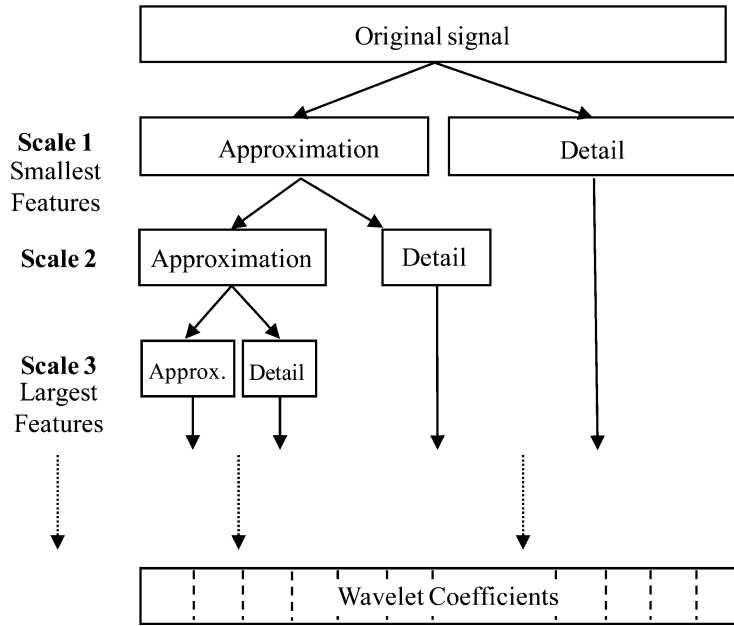
three components, low-pass filters $L(n)$, high-pass filters $H(n)$, and dyadic decimation. By passing the input signal through this pair of filters, the projection of the original signal onto the scaling and wavelet functions for the multiresolution analysis is performed. Dyadic decimation, or down-sampling, removes every odd member of a sequence, thus halving the original number of samples. The low-pass filter resembles a moving average, while the high-pass filter extracts the detailed information contained in the signal. The discrete wavelet transform operates by taking a sequence of values, applying $L(n)$ and $H(n)$ and then repeating this same procedure to the approximation coefficients. In this way, the original signal vector is *smoothed and halved* through L, and the vector of approximation coefficients is again *smoothed and halved* through L. Successive application of the low-pass filter results in the approximation coefficients, becoming an increasingly smooth version of the original signal. At the same time as smoothing the signal, each iteration extracts the high frequency information in the data. The repeated application of L, followed by H is, in effect, a band-pass filter. The result of applying high-/low-pass filters to a signal is a set of coefficients describing the details of the signals $\mathbf{D}_L$ and a second set describing the approximations of the signals $\mathbf{A}_L$. The original signal s can then be represented by

$$x(t) = \sum_{j=1}^{L} D_j(t) + A_L(t)$$

where D_j and A_j are referred to as the jth level wavelet details and approximation, respectively.

Figure 1 shows schematically the multiresolution-based wavelet decomposition.

One of the most popular choices of wavelets are those of the Daubechies' family. These wavelets are compactly supported in the time domain and have good frequency domain decay. Moreover, Daubechies' wavelets (DaubN) possess a different type of smoothness which is determined by the vanishing moments N. This makes it possible to match the wavelet smoothness to the smoothness of the signals to be analyzed. The signal can then be decomposed

Multiscale Multivariate Statistical Process Control, Fig. 1 Schematic of multiresolution wavelet decomposition


into its contributions from multiple scales as a weighted sum of dyadically discretized orthonormal basis functions:

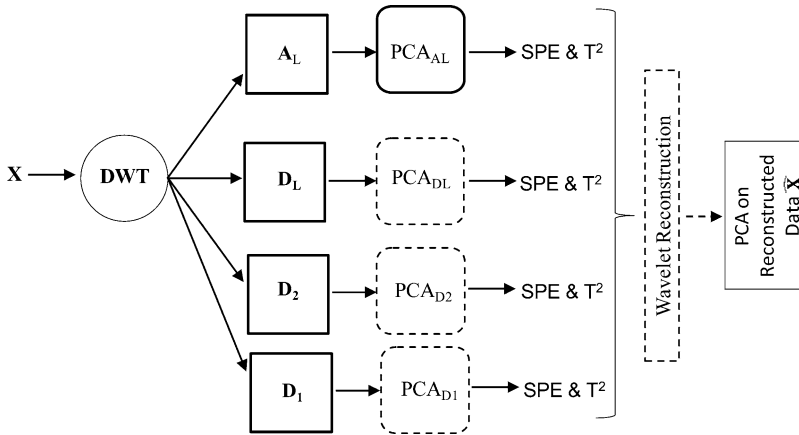
$$x(t) = \sum_{m=1}^{L} \sum_{k=1}^{N} d_{mk} \psi_{mk}(t) + \sum_{k=1}^{N} a_{lk} \varphi_{lk}(t)$$

where $x(t)$ represents the process measurements, d_{mk} represents the wavelet or detail signal coefficient at scale m and location k, and a_{Lk} represent the scaled signal or scaling function coefficient of $\phi(t)$ at the coarsest scale L and location k. The scaling function, or father wavelet, ϕ_{mk} captures the low-frequency content of the original signal that is not captured by wavelets at the corresponding or finer scales.

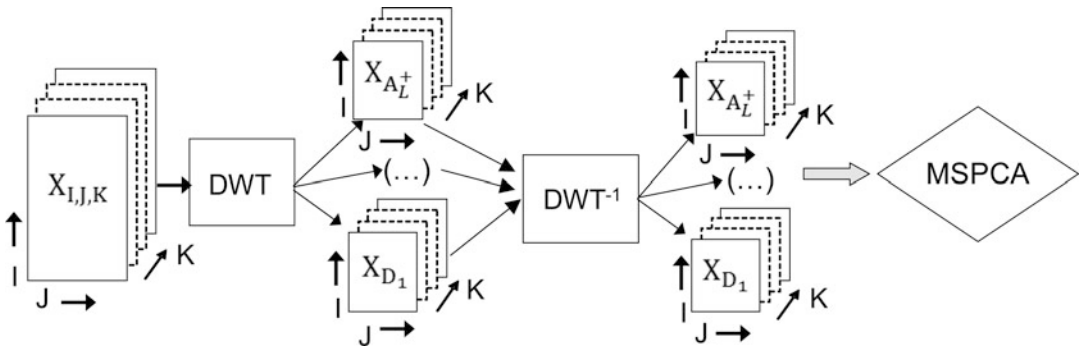
The wavelet transformation is applied to decompose a multivariate signal $\mathbf{X}$ into its approximate, $\mathbf{A}_1$ to $\mathbf{A}_L$, and detail, $\mathbf{D}_1$ to $\mathbf{D}_L$, coefficients for the first to Lth level, respectively. For more information, see Bakshi (1998), Misra et al. (2002) and Aradhye et al. (2003). Figure 2 shows a schematic representation of a typical MSPCA multivariate statistical process control scheme.

An example of the application of multiway-multiscale MPCA to a benchmark-fed batch

fermentation process (Birol et al. http://www.chee.iit.edu~control/software.html) was presented by Alawi and Morris (2007). The application used a combination of multiblock statistical modeling approaches together with multiscale-multiway batch monitoring. Figure 3 shows the multiscale-multiway monitoring scheme for process monitoring and fault detection. At every time point, the batch process variables are decomposed into scales to the wavelet domain and then reconstructed back to the time domain. The scales/details and the approximations are collected into separate matrices (blocks). Multiblock PCA is then applied to the wavelets details and approximation. Fault detection based on the T_s^2 and Q_s statistics was used along with contribution plots incorporating confidence bounds to enhance fault diagnosis.

Figure 4 compares the monitoring statistics for the multiscale-multiway PCA and conventional multiway PCA for a slowly drifting sensor fault showing the potential for multiscale MPCA (MSPCA) in being able to detect faster subtle process and sensor faults than conventional multiway MSPC. It is noted that sensor drift is confined to one scale band at low frequency. It has been observed that multiscale approaches appear to provide little improvement if a fault effect is


Multiscale Multivariate Statistical Process Control, Fig. 2 Schematic representation of multiscale PCA-based MSPC



Multiscale Multivariate Statistical Process Control, Fig. 3 Multiscale-multiway batch process monitoring scheme

spread over more than one frequency band or the fault effect occurs mainly in a scale with dominant variance. Thus, a monitoring method that gives the best detection and identification of faults will depend on the fault characteristics with multiscale approaches, providing an advantage when the faults localized in frequency or that appear in scales that normally have small variance.

Other Applications of Multiscale MPCA

There have a number of nonlinear extensions. For example, multiscale PLS approaches have been developed, e.g., Teppola and Minkkinen (2000) and Lee et al. (2009). Nonlinear approaches have also been explored. For example, Lee et al. (2004) proposed a batch monitoring approach using multiway kernel principal component analysis, Shao et al. (1999) proposed a wavelet-based nonlinear PCA algorithm, Choi et al. (2008) described a study of a kernel-based MSPCA algorithm for nonlinear multiscale monitoring, and most recently Zhang and Ma (2011) compared fault diagnosis of nonlinear processes using multiscale KPCA and multiscale KPLS. Wavelet multiscale approaches have also been widely discussed in spectroscopic data processing (Shao et al. 2004).

Multi-vehicle Routing

Emilio Frazzoli[1] and Marco Pavone[2]
[1]Massachusetts Institute of Technology, Cambridge, MA, USA
[2]Stanford University, Stanford, CA, USA

Abstract

Multi-vehicle routing problems in systems and control theory are concerned with the design of control policies to coordinate several vehicles

moving in a metric space, in order to complete spatially localized, exogenously generated tasks in an efficient way. Control policies depend on several factors, including the definition of the tasks, of the task generation process, of the vehicle dynamics and constraints, of the information available to the vehicles, and of the performance objective. Ensuring the stability of the system, i.e., the uniform boundedness of the number of outstanding tasks, is a primary concern. Typical performance objectives are represented by measures of quality of service, such as the average or worst-case time a task spends in the system before being completed or the percentage of tasks that are completed before certain deadlines. The scalability of the control policies to large groups of vehicles often drives the choice of the information structure, requiring distributed computation.

Keywords

Cooperative control; Decentralized control; Dynamic routing; Networked robots; Task allocation

Introduction

Multi-vehicle routing problems in systems and control theory are concerned with the design of control policies to coordinate several vehicles moving in a metric space, in order to complete spatially localized, exogenously generated tasks in an efficient way. Key features of the problem are that tasks arrive *sequentially* over time and planning algorithms should provide *control policies* (in contrast to preplanned routes) that prescribe how the routes should be updated as a function of those inputs that change in real time. This problem is usually referred to as dynamic vehicle routing (DVR). In DVR problems, ensuring the stability of the system, i.e., the uniform boundedness of the number of outstanding tasks, is a primary concern.

Motivation and Background

As a motivating example, consider the following scenario: a team of unmanned aerial vehicles

(UAVs) is responsible for investigating possible threats over a region of interest. As possible threats are detected, by intelligence, high-altitude or orbiting platforms, or by ground sensor networks, one of the UAVs must visit its location and investigate the cause of the alarm, in order to enable an appropriate response if necessary. Performing this task may require the UAV not only to fly to the possible threat's location but also to spend additional time on site. The objective is to minimize the average time between the appearance of a possible threat and the time one of the UAVs completes the close-range inspection task. Variations may include priority levels, time windows during which the inspection task must be completed, and sensors with limited range.

In order to perform the required mission, the UAVs (or, more in general, mission control) need to repeatedly solve three *coupled* decision-making problems:

1. **Task allocation:** which UAV shall pursue each task? What policy is used to assign tasks to UAVs? How often should the assignment be revised?
2. **Service scheduling:** given the list of tasks to be pursued, what is the most efficient ordering of these tasks?
3. **Loitering paths:** what should UAVs without pending assignments do?

The optimization process must take into account, for example, algebraic or differential constraints (such as obstacle avoidance or bounded curvature, respectively), sensing constraints, communication constraints, and energy constraints. Furthermore, one might require a decentralized control architecture.

DVR problems, including the above UAV routing problem, are generally *intractable* due to their multifaceted combinatorial, differential, and stochastic nature, and consequently solution approaches have been devised that look either at heuristic algorithms or at approximation algorithms with some guarantee on their performance.

Related Problems

DVR problems represent the dynamic counterpart of the well-known static vehicle routing

problem (VRP), whereby (i) a team of n vehicles is required to service a set of n_T "static" tasks in a metric space, (ii) each task requires a certain amount of on-site service, (iii) and the goal is to compute a set of routes that minimizes the cost of servicing the tasks; see Toth and Vigo (2001) for a thorough introduction to this problem. The VRP is *static* in the sense that vehicle routes are computed assuming that no new tasks arrive. The VRP is an important research topic in the operations research community.

Approaches for Multi-vehicle Routing

Broadly speaking, there are three main approaches available in the literature to tackle dynamic vehicle routing problems. The first approach relies on heuristic algorithms. In the second approach, called "competitive analysis approach," routing policies are designed to minimize the *worst-case* ratio between their performance and the performance of an optimal off-line algorithm which has a priori knowledge of the entire input sequence. In the third approach, the routing problem is embedded within the framework of queueing theory. Routing policies are then designed to *stabilize* the system in terms of uniform boundedness of the number of outstanding tasks and to minimize typical queueing-theoretical cost functions such as the *expected time* the tasks remain in the queue. Since the generation of tasks and motion of the vehicles is within an Euclidean space, one can refer to this third approach as "spatial queueing theory."

Heuristic Approach

The main aspect of the heuristic approach is that routing algorithms are evaluated primarily via numerical, statistical and experimental studies, and formal performance guarantees are not available. A naïve, yet reasonable approach to design a heuristic algorithm for DVR would be to adapt classic queueing policies. However, perhaps surprisingly, this adaptation is not at all straightforward. For example, routing algorithms based on a first-come-first-served policy, whereby tasks are fulfilled in the order in which they arrive, are unable to stabilize the system for all stabilizable task arrival rates, in the sense that with such routing algorithms the average number of tasks grows over time without bound, even though there exist alternative routing algorithms that would maintain the number of tasks uniformly bounded (Bertsimas and van Ryzin 1991).

The most widely applied approach is to combine static routing methods (e.g., VRP-like methods, nearest neighbor strategies, or genetic algorithms) and sequential re-optimization, where the re-optimization horizon is chosen heuristically. In particular, greedy nearest neighbor strategies, whose formal characterization still represents an open problem, are known to perform particularly well in some notable cases (Bertsimas and van Ryzin 1991). However, the joint selection of a static routing method and of the re-optimization horizon in the presence of vehicle and task constraints (e.g., differential motion constraints, or task priorities) makes the application of this approach far from trivial. For example, one can show that an erroneous selection of the re-optimization horizon can lead to pathological scenarios where no task *ever* receives service (Pavone 2010). Additionally, performance criteria in dynamic settings commonly differ from those of the corresponding static problems. For example, in a dynamic setting, the time needed to complete a task may be a more important factor than the total vehicle travel cost.

Competitive Analysis Approach

The distinctive feature of the competitive analysis approach is the method used to evaluate an algorithm's performance, which is called *competitive analysis*. In competitive analysis, the performance of a (causal) algorithm is compared to the performance of a corresponding off-line algorithm (i.e., a non-causal algorithm that has a priori knowledge of the entire input) in the worst-case scenario. Specifically, an algorithm is c-competitive if its cost on *any* problem instance is at most c times the cost of an optimal off-line algorithm:

$$\text{Cost}_{\text{causal}}(I) \leq c\, \text{Cost}_{\text{optimal off-line}}(I),$$

$$\textit{for all} \text{ problem instances } I.$$

In the recent past, several dynamic vehicle routing problems have been successfully studied in this framework, under the name of the online traveling repairman problem (Jaillet and Wagner 2006), and many interesting insights have been obtained. However, the competitive analysis approach has some potential disadvantages. First, competitive analysis is a *worst-case* analysis; hence, the results are often overly pessimistic for normal problem instances, and potential statistical information about the problem (e.g., knowledge of the spatial distribution of future tasks) is often neglected. Second, the worst-case analysis usually requires a *finite* horizon problem formulation, which precludes the study of useful properties such as stability. Third, competitive analysis is used to bound the performance relative to an optimal *off-line* algorithm, which, by being non-causal, does *not* belong to the feasible set of routing algorithms one is optimizing over. Hence, with this approach one minimizes the "cost of causality" in the worst-case scenario, but not necessarily the worst-case cost (which would require comparison with an optimal *causal* routing algorithm). Finally, many important real-world constraints for DVR, such as time windows, priorities, differential constraints on vehicle's motion, and the requirement of teams to fulfill a task, have so far proved to be too complex to be considered in the competitive analysis framework (Golden et al. 2008, page 206). Some of these drawbacks have been recently addressed by Van Hentenryck et al. (2009) where a combined stochastic and competitive analysis approach is proposed for a general class of combinatorial optimization problems and is analyzed under some technical assumptions.

Spatial Queueing Theory

Spatial queueing theory embeds the dynamic vehicle routing problem within the framework of queueing theory. Spatial queueing theory consists of three main steps, namely, development of a spatial queueing model, establishment of fundamental limitations of performance, and design of algorithms with performance guarantees. More specifically, the formulation of a model entails detailing four main aspects:

1. A model for the *dynamic* component of the environment: this is usually achieved by assuming that new events are generated (either adversarially or stochastically) by an exogenous process.
2. A model for targets/tasks: tasks are usually modeled as points in a physical environment distributed according to some (possibly unknown) distribution, might require a certain level of on-site service time, and can be subject to a variety of constraints, e.g., time windows, priorities, etc.
3. A model for the vehicles and their motion: besides their number, one needs to specify whether the vehicles are subject to algebraic (e.g., obstacles) or differential (e.g., minimum turning radius) constraints, sensing constraints, and fuel constraints. Also, the control could be centralized (i.e., coordinated by a central station) or decentralized and subject to communication constraints.
4. Performance criterion: examples include the minimization of the waiting time before service, loss probabilities, expectation-variance analysis, etc.

Once the model is formulated, one seeks to characterize fundamental limitations of performance (in the form of lower bounds for the best achievable cost); the purpose of this step is essentially twofold: it allows the quantification of the degree of optimality of a routing algorithm and provides structural insights into the problem. As for the last step, the design of a routing algorithm usually relies on a careful combination of static routing methods with sequential re-optimization. Desirable properties for the static methods are the following: (i) the static problem can be solved (at least approximately) in polynomial time and (ii) the static method is amenable to a statistical characterization (this is essential for the computation of performance bounds). Formal performance guarantees on a routing algorithm are then obtained by

quantifying the ratio between an upper bound on the cost delivered by that algorithm and a lower bound for the best achievable cost. Such a ratio, being an estimate of the degree of optimality of the algorithm, should be close to one and possibly independent of system parameters. The proposed algorithms are finally evaluated via numerical, statistical and experimental studies, including Monte-Carlo comparisons with alternative approaches.

An interesting feature of this approach is that the performance analysis usually yields scaling laws for the quality of service in terms of model data, which can be used as useful guidelines to select system parameters when feasible (e.g., number of vehicles).

In order to make the model tractable, the arrival process of tasks is assumed stationary (with possibly unknown parameters) with statistically independent arrival times. These assumptions, however, can be unrealistic in some scenarios, in which case the competitive analysis approach may represent a better alternative. From a technical standpoint, one should note that spatial queueing models are *inherently* different from traditional, nonspatial queueing models. The main reason is that in spatial queueing models, the "service time" per task has both a *travel* and an *on-site* component. Although the on-site service requirements can often be modeled as "statistically" independent, the travel times are *inherently* statistically coupled. Hence, in contrast to standard queueing models, service times in spatial queueing models are statistically *dependent*, and this deeply affects the solution to the problem.

Pioneering work in this context is that of Bertsimas and van Ryzin (1991), who introduced queueing methods to solve the baseline DVR problem (a vehicle moves along straight lines and visits tasks whose time of arrival, location, and on-site service are stochastic; information about task location is communicated to the vehicle upon task arrival). Next section provides an overview of the application of spatial queueing theory to such simplified DVR problem, referred to in the literature as dynamic traveling repairman problem (DTRP).

Applying Spatial Queueing Theory to DVR Problems

Spatial Queueing Theory Workflow for DTRP

Model

The DTRP, which, incidentally, captures well the salient features of the UAV scenario outlined in the Motivation Section, can be modeled as follows. In a geographical region $\mathcal{Q}$ of area $\mathcal{A}$, a dynamic process generates spatially localized tasks. The process generating tasks is modeled as a spatio-temporal Poisson process, i.e., (i) the time between consecutive generation instants has an exponential distribution with intensity $\lambda > 0$ and (ii) upon arrival, the locations of tasks are independently and uniformly distributed in $\mathcal{Q}$. The location of the new tasks is assumed to be immediately available to a team of n servicing vehicles. The vehicles provide service in $\mathcal{Q}$, traveling at a speed at most equal to v; the vehicles are assumed to have unlimited fuel and task-servicing capabilities. Each task requires an independent and identically distributed amount of on-site service with finite mean duration $\bar{s} > 0$. A task is completed when one of the vehicles moves to its location and performs its on-site service. The objective is to design a *routing policy* that maximizes the quality of service delivered by the vehicles in terms of the average steady-state time delay $\overline{T}$ between the generation of a task and the time it is completed (in general, in a dynamic setting, the focus is on the quality of service as perceived by the "end user," rather than, for example, fuel economies achieved by the vehicles). Other quantities of interest are the average number $\overline{n_{\mathrm{T}}}$ of tasks waiting to be completed and the waiting time $\overline{W}$ of a task before its location is reached by a vehicle. These quantities, however, are related according to $\overline{T} = \overline{W} + \bar{s}$ (by definition) and by Little's law, stating that $\overline{n_{\mathrm{T}}} = \lambda \overline{W}$, for stable queues.

The system is considered stable if the expected number of waiting tasks is uniformly bounded at all times, or equivalently, that tasks are removed from the system at least at the same rate at which they are generated. In the case at hand,

M

the time to complete a task is the sum of the time to reach its location (which depends on the routing policy) plus the time spent at that location in on-site service (which is independent of the routing policy). Since, by definition, the service time is no shorter than the on-site service time $\overline{s}$, then a weaker necessary condition for stability is $\varrho := \lambda \overline{s}/n < 1$; the quantity ϱ measures the fraction of time the vehicles are performing on-site service. Remarkably, it turns out that this is also a sufficient condition for stability, in the sense that, if this condition is satisfied, one can find a stabilizing policy. Note that this stability condition is independent of the size and shape of $\mathcal{Q}$ and of the speed of the vehicles.

Fundamental Limitations of Performance

To derive lower bounds, the main difficulty consists in bounding (possibly in a statistical sense) the amount of time spent to reach a target location. The derivation of these bounds becomes simpler in asymptotic regimes, i.e., looking at cases when $\varrho \to 0^+$ and $\varrho \to 1^-$, which are often called "light-load" and "heavy-load" conditions, respectively.

Consider first the case in which $\varrho \to 0^+$ (light-load regime). A set of n points is called the n-median of $\mathcal{Q}$ if it globally minimizes the expected distance between a random point sampled uniformly from $\mathcal{Q}$ and the closest point in such set. In other words, the n-median of $\mathcal{Q}$ globally minimizes the function

$$
\begin{aligned}
&H_n(p_1, p_2, \ldots, p_n) \\
&\quad := \mathbb{E}\left[\min_{k \in \{1, \ldots, n\}} \|p_k - q\|\right] \\
&\quad = \frac{1}{A} \int_{\mathcal{Q}} \min_{k \in \{1, \ldots, n\}} \|p_k - q\| \, dq.
\end{aligned}
$$

Let H_n^* be the global minimum of this function. Geometric considerations show that H_n^* scales proportionally to $\sqrt{A/n}$.

Incidentally, the n-median of $\mathcal{Q}$ induces a Voronoi partition that is called *Median Voronoi Tessellation*, whose importance will become clear in the next section. Recall that the Voronoi diagram of $\mathcal{Q}$ induced by points $(p_1, \ldots, p_n)$ is defined by

$$
\begin{aligned}
V_i = \Big\{ q \in \mathcal{Q} \big| \, \|q - p_i\| &\le \|q - p_j\|, \; \forall j \ne i, \\
j &\in \{1, \ldots, n\} \Big\},
\end{aligned}
$$

where V_i is the region associated with the i-th "generator" point p_i (see also ▶ Optimal Deployment and Spatial Coverage). The distance H_n^* certainly provides a lower bound on the expected distance traveled by a vehicle to reach a task, and hence one obtains the lower bound

$$
\overline{T} \ge \frac{H_n^*}{v} + \overline{s}.
$$

This lower bound is tight in light-load conditions ($\varrho \to 0^+$), as it will be seen in the next section.

Consider now the case in which $\varrho \to 1^-$ (heavy load). Let $\overline{D}$ be the average travel distance per task for some routing policy. By using arguments from geometrical probability (independent of algorithms), one can show that $\overline{D} \ge \beta_2 \sqrt{A}/\sqrt{2\overline{n_T}}$ as $\varrho \to 1^-$, where β_2 is a constant that will be specified later. As discussed, for stability, one needs $\overline{s} + \overline{D}/v < n/\lambda$. Combining the stability condition with the bound on the average travel distance per task, one obtains

$$
\overline{s} + \frac{\beta_2 \sqrt{A}}{v \sqrt{2\overline{n_T}}} \le \frac{n}{\lambda}.
$$

Since, by Little's law, $\overline{n_T} = \lambda \overline{W}$ and $\overline{T} = \overline{W} + \overline{s}$, one finally obtains (recall that $\varrho = \lambda \overline{s}/n$):

$$
\overline{T} \ge \frac{\beta_2^2}{2} \frac{A}{v^2} \frac{\lambda}{n^2 (1 - \varrho)^2} + \overline{s}, \qquad (\text{as } \varrho \to 1^-).
$$

A salient feature of the above lower bound is that it scales *quadratically* with the number of vehicles (as opposed to the square-root scaling law one has in light-load conditions); note, however, that congestion effects are not included in this model. This bound also shows that the quality of service, which is proportional to $1/(1 - \varrho)^2$, degrades much faster as the target load increases than in nonspatial queueing systems (where the growth rate is proportional to $1/(1 - \varrho)$).

Design of Routing Algorithms

The design of an optimal light-load policy essentially relies on mimicking the proof strategy employed for the light-load lower bound. Specifically, a routing policy whereby (1) one vehicle is assigned to each of the n median locations of $\mathcal{Q}$, (2) new tasks are assigned to the nearest median location and its corresponding vehicle, and (3) each vehicle services tasks according to a first-come-first-served policy is asymptotically optimal, i.e.,

$$\overline{T} \to \frac{H_n}{v} + \overline{s}, \qquad (\text{as } \varrho \to 0^+).$$

Note that under this strategy "regions of dominance" are implicitly assigned to vehicles according to a Median Voronoi Tessellation.

The heavy-load case is more challenging. Consider, first, the following single-vehicle routing policy, based on a partition of $\mathcal{Q}$ into $p \geq 1$ subregions $\{\mathcal{Q}_1, \mathcal{Q}_2, \ldots, \mathcal{Q}_p\}$ of equal area A/p. Such a partition can be obtained, e.g., as sectors centered at the median of $\mathcal{Q}$. Define a cyclic ordering for the subregion, such that, e.g., if the vehicle is in region $\mathcal{Q}_i$, the "next" region is $\mathcal{Q}_j$, where j follows i in the cyclic ordering (in other words, $j = (i + 1) \bmod p$).

---

1. If there are no outstanding tasks, move to the median of the region $\mathcal{Q}$.
2. Otherwise, visit the "next" subregion; subregions with no tasks are skipped. Compute a minimum-length path from the vehicle's current position through all the outstanding tasks in that subregion. Complete all tasks on this path, ignoring new tasks generated in the meantime. Repeat.

The problem of computing the shortest path through a number of points is related to the well-known traveling salesman problem (TSP). While the TSP is a prototypically hard combinatorial optimization problem, it is well known that the Euclidean version of the problem can be approximated efficiently (Vazirani 2001). Furthermore, the length $\text{ETSP}(n_T)$ of a Euclidean TSP through

n_T points independently and uniformly sampled in $\mathcal{Q}$ is known to satisfy the following property:

$$\lim_{n_T \to \infty} \text{ETSP}(n_T)/\sqrt{n_T} = \beta_2 \cdot \sqrt{A}, \quad \text{almost surely,}$$

where $\beta_2 \approx 0.712$ is a constant (the same β_2 constant that appeared in the previous section) (Steele 1990).

It can be shown that, using the above routing policy, the average system time $\overline{T}$ satisfies

$$\overline{T} \leq \gamma(p) \frac{A}{v^2} \frac{\lambda}{(1 - \varrho)^2} + \overline{s}, \qquad (\text{as } \varrho \to 1^-),$$

where $\gamma(1) = \beta_2^2$ and $\gamma(p) \to \beta_2^2/2$ for large p. These results critically exploit the statistical characterization of the length of an optimal TSP tour. Hence, the proposed policy achieves a quality of service that is arbitrarily close to the optimal one, in the asymptotic regime of heavy load (and, indeed, also of light load).

The above single-vehicle routing policies can be fairly easily lifted to an efficient multi-vehicle routing policy. The key idea (akin to the one in the light-load case) is to (1) partition the workspace into n *regions of dominance* (with disjoint interiors and whose union is $\mathcal{Q}$), (2) assign one vehicle to each region, and (3) have each vehicle follow a single-vehicle routing policy within its own region. This approach leads to the following multi-vehicle routing policy for the DTRP problem:

---

1. Partition $\mathcal{Q}$ into n regions of dominance of *equal area* and assign one vehicle to each region.
2. Each vehicle executes a single-vehicle DTRP policy in its own subregion.

Using as single-vehicle policy the routing policy described above, the average system time $\overline{T}$ in heavy-load satisfies

$$\overline{T} \leq \gamma(p) \frac{A}{v^2} \frac{\lambda}{n^2 (1 - \varrho)^2} + \overline{s}, \qquad (\varrho \to 1^-).$$

Hence, by comparing this result with the corresponding lower bound, one concludes that a

simple partitioning strategy leads to a multi-vehicle routing policy whose performance is arbitrarily close to the optimal one in heavy load.

Mode of Implementation

The scalability of the control policies to large groups of vehicles often requires a distributed implementation of multi-vehicle routing strategies. For the DTRP, a distributed implementation can be obtained by devising *decentralized algorithms for environment partitioning*. In the solution proposed in Pavone (2010), power diagrams are the key geometric concept to obtain, in a decentralized fashion, partitions suitable for both the light-load case (requiring, as seen before, a Median Voronoi Tessellation) and the heavy-load case (requiring an equal-area partition). The power diagram of $\mathcal{Q}$ is defined as

$$V_i = \left\{ q \in \mathcal{Q} \mid \|q - p_i\|^2 - w_i \leq \|q - p_j\|^2 - w_j, \\ \forall j \neq i, \; j \in \{1, \ldots, n\} \right\},$$

where $(p_i, w_i) \in \mathcal{Q} \times \mathbb{R}$ are a set of "power points" and V_i is the subregion associated with the i-th power point. Note that power diagrams are a generalization of Voronoi diagrams: when all weights are equal, the power diagram and the Voronoi diagram are identical. The basic idea, then, is to associate to each vehicle i a *virtual* power point, which is an artificial (or logical) variable whose value is locally controlled by the i-th vehicle. The cell V_i becomes the region of dominance for vehicle i, and each vehicle updates its own power point according to a *decentralized* gradient-descent law with respect to a coverage function (▶ Optimal Deployment and Spatial Coverage), until the desired partition is achieved. The reader is referred to Pavone (2010) for more details.

Extensions and Discussion

By integrating additional ideas from dynamics, teaming, and distributed algorithms, the spatial queueing theory approach has been recently applied to scenarios with complex models for the tasks such as time constraints, service priori-

ties, translating tasks, and adversarial generation; has been extended to address aspects concerning robotic implementation such as complex vehicle dynamics, limited sensing range, and team forming; and has even been tailored to integrate humans in the design space; see Bullo et al. (2011) and references therein. Despite the significant modeling differences, the "workflow" is essentially the same as in the DTRP: a queueing model that captures the salient features of the problem at hand, characterization of the fundamental limitations of performance, and design of algorithms with provable performance bounds. The last step, as for the DTRP, often involves lifting a single-vehicle policy to a multi-vehicle policy through the strategy of environment partitioning. Within this context, a number of partitioning schemes and corresponding *decentralized* partitioning algorithms relevant to a large variety of DVR problems are discussed in Pavone et al. (2009).

This workflow efficiently and transparently *decouples* the three decision-making problems mentioned in the Introduction Section, i.e., "task allocation," "service scheduling," and "loitering paths." In fact, task allocation is addressed via the strategy of environment partitioning, service scheduling is addressed by applying a single-vehicle routing policy within the individual regions of dominance, and the loitering paths resolve in placing the vehicles at or around specific points within the dominance regions (e.g., the median). Note, however, that in some important cases, e.g., DVR problems where goods have to be transported from a pickup location to a delivery location or where vehicles are differentially constrained and operate in a "congested" workspace, multi-vehicle policies that rely on static partitions perform poorly or are not even feasible (Pavone et al. 2009), and task allocation and service scheduling need to be addressed as tightly coupled.

Through spatial queueing theory one is usually able to characterize the performance of multi-vehicle routing policies in asymptotic regimes. To ensure "satisfactory" performance under general operation conditions, a common strategy is to consider heuristic modifications

to a baseline asymptotically efficient routing policy in such a way that, on the one hand, asymptotic performance is preserved, and, on the other hand, light- and heavy-load performances are "smoothly" and efficiently blended in the intermediate load case. The interested reader can find more information in Bullo et al. (2011).

Summary and Future Directions

The three main approaches available to tackle DVR problems are (i) heuristic algorithms, (ii) competitive analysis, and (iii) spatial queueing theory. Broadly speaking, the competitive analysis approach is well suited when worst-case guarantees are sought, e.g., because there is not enough statistical information about the problem at hand. Spatial queueing theory represents a powerful alternative in cases where it is possible to leverage statistical information and one seeks average-case guarantees. Finally, for some problems the complexity of the model makes an analytical treatment very difficult, in which case the only option is to resort to an heuristic approach (possibly relying on insights derived by applying competitive analysis and/or spatial queueing theory to a simplified version of the problem).

Future directions include the extension of the three aforementioned approaches to increasingly complex problem setups, for example, higher-fidelity vehicle dynamics and environments and sophisticated sensing and communication constraints, novel applications (e.g., search and rescue missions, map maintenance, and pursuit-evasion), and inclusion of game-theoretical tools to address adversarial scenarios. Specifically, for the spatial queueing theory approach, key future directions include the problem of addressing optimality of performance in intermediate regimes (current optimality results are only available either in the light or heavy-load regimes), online estimation of the statistical parameters (e.g., spatial distribution of the tasks), and formulations that take into account second-order moments and large-deviation probabilities.

Abstract

Game theory plays a central role in studying systems with a number of interacting players competing for a common resource. A communication network serves as a prototypical example of such a system, where the common resource is the network, consisting of nodes and links with limited capacities, and the players are the computers, web servers, and other end hosts who want to transfer information over the shared network. In this entry, we present several examples of game-theoretic interaction in communication networks and present a simple mathematical model to study one such instance, namely, resource allocation in the Internet.

Keywords and Phrases

Introduction

A communication network can be viewed as a collection of resources shared by a set of competing users. If the network were totally unregulated, then each user would attempt to grab as many resources in the network as possible, resulting in poor network performance, a situation commonly referred to as the *tragedy of the commons* (Hardin 1968). In reality, there is a carefully designed set of network protocols and pricing mechanisms which provide incentives to users to act in a socially responsible manner. Since game theory is the mathematical discipline which studies the interactions between selfish users, it is a natural tool to use to design these network control mechanisms. We now provide a few examples of network problems which naturally lend themselves to game-theoretic analysis. Later, we will elaborate on the game-theoretic formulation of one of these examples.

- *Resource Allocation:* A network such as the Internet is a collection of links, where each link has a limited data-carrying capacity, usually measured in bits per second.

The Internet is shared by billions of users, and the actions of these users have to be regulated so that they share the resources in the network in a fair manner. Equivalently, this problem can be viewed as one in which a network designer has to design a collection of protocols so that the users of the network can equitably allocate the available resources among themselves without the intervention of a central authority. Such protocols are built into every computer connected to the Internet today, to allow for seamless operation of the network. The problem of designing such protocols can be posed as a game-theoretic problem in which the players are the network and the traffic sources using the network (Kelly 1997).

- *Routing Games:* Finding appropriate routes for each user's data traffic is a particular form of resource allocation mentioned above. However, routing has applications beyond communication networks (with the other major application area being transportation networks), so it is useful to discuss routing separately. In communication networks, each user may attempt to find the minimum-delay route for its traffic, with help from the network, to minimize the delay experienced by its packets. In a transportation network, each automobile on the road attempts to take the path of least congestion through the network. An active area of research in game theory is one which tries to understand the impact of individual user decisions on the global performance of the network (Roughgarden 2005). An interesting result in this regard is the *Braess paradox* which is an example of a road transportation network in which the addition of a road leads to increased delays when each user selfishly choose a route to minimize its delay. Of course, if routes are chosen to minimize the overall delay experienced in the network such a paradox will not arise.

- *Peer-to-Peer Applications:* Many studies have indicated that file sharing between users (also known as peers) directly, without using a centralized web site such as YouTube, is a dominant source of traffic in the Internet.

For such a peer-to-peer service to work, each peer should not only download files from others, but should also be willing to sacrifice some of its resources to upload files to others. Naturally, peers would prefer to only download and not upload to minimize their resource usage. The design of incentive schemes to induce users to both download and upload files is another example of a game-theoretic problem in a network (Qiu and Srikant 2004).

- *Network Economics:* In addition to end-user interaction, Internet service providers (ISPs) have to interact with each other to allow their customers access to all the web sites in the world. For example, one ISP may have a customer who wants to access a web site connected to another ISP. In this case, the data traffic must cross ISP boundaries, and thus, one ISP has to transport data destined for a customer of another ISP. Thus, ISPs must be willing to contribute resources to satisfy the needs of customers who do not directly pay them. In such a situation, ISPs must have bilateral agreements (commonly known as *peering agreements*) to ensure that the selfish interest of each ISP to minimize its resource usage is aligned with the needs of its customers. Again, game theory is the right tool to study such inter-ISP interactions (Courcoubetis and Weber 2003).

- *Spectrum Sharing:* Large portions of the radio spectrum are severely underutilized. Typically, portions of the spectrum are assigned to a primary user, but the primary user does not use it most of the time. There has been a surge of interest recently in the concept of *cognitive radio,* whereby radios are cognitive of the presence or absence of the primary user, and when the primary user is absent, another radio can use the spectrum to transmit its data. When there are many users and the available spectrum is split into many channels, it is impossible for users to perfectly coordinate their transmissions to achieve maximum network utilization. In these situations, game-theoretic protocols which take into account the noncooperative behavior of the users can be

designed to allow secondary users to access the available channels as efficiently as possible (Saad et al. 2009).

In the next section, we will elaborate on one of the applications above, namely, resource allocation in the Internet, and show how game-theoretic modeling can be used to design fair resource sharing.

Resource Allocation and Game Theory

Consider a network consisting of L links, with link l having capacity c_l. Suppose that there are R users sharing the network, with each user r being characterized by a set of links which connect the user's source to its destination. Since each user uses a fixed route in our model, we will use r to denote both the user and the route used by the user. We use the notation $l \in r$ to denote that link l is a part of route r. Let x_r denote the rate at which user r transmits data. Thus, we have the following natural constraints, which state that the total data rate on any link must be less than or equal to the capacity of the link:

$$\sum_{r:l \in r} x_r \le c_l, \qquad \forall l. \tag{1}$$

Associated with each user is a concave utility function $U_r(x_r)$ which is the utility that user r derives by transmitting data at rate x_r. The network utility maximization problem is to solve

$$\max_{x \ge 0} \sum_r U_r(x_r), \tag{2}$$

subject to the constraint (1). In (2), x denotes the vector $(x_1, x_2, \ldots, x_R)$ and $x \ge 0$ means that each component of x must be greater than or equal to zero. Note that the goal of the network in (2) is to maximize the sum of the utilities of the users in the network.

Let p_l be the Lagrange multiplier corresponding to the capacity constraint in (1) for link l. Then the Lagrangian for the problem is given by

$$L(x, p) = \sum_r U_r(x_r) - \sum_l p_l(y_l - c_l), \tag{3}$$

where we have used the notation $y_l := \sum_{r:l \in r} x_r$ to denote the total data rate on link l. If p is known, then the optimal x can be calculate by solving

$$\max_{x \ge 0} L(x, p).$$

Notice that the optimal solution for each x_r can be obtained by solving

$$\max_{x_r \ge 0} U_r(x_r) - q_r x_r, \tag{4}$$

where $q_r = \sum_{l \in r} p_l$. Thus, if the Lagrange multipliers are known, then the network utility maximization can be interpreted as a game in the following manner. Suppose that the network charges each user q_r dollars for every bit transmitted by user r though the network. Then, $q_r x_r$ is the dollars per second spent by the user if x_r is measured in bits per second. Interpreting $U_r(x_r)$ as the dollars per second that the user is willing to pay for transmitting at rate x_r, the optimization problem in (4) is the problem faced by user r which wants to maximize its net utility, i.e., utility minus cost. Thus, the individual optimal solution for each user is also the solution to the network utility maximization problem. The above game-theoretic interpretation of the network utility maximization problem is somewhat trivial since, given the p_l's or q_r's, there is no interaction between the users. Of course, this interpretation relies on the ability of the network to compute p. We next present a scheme to compute p, which couples the users closely and thus allows for a richer game-theoretic interpretation.

Suppose that the network wants to compute p but does not have access to the utility functions of the users. The network asks each user r to bid an amount w_r which is interpreted as the dollars per second that the user is willing to pay. The network then assumes that user r's utility function is $w_r \log x_r$ and solves the network utility maximization. While this choice of utility function may seem arbitrary, the resulting solution x has a number of attractive properties, including a form of fairness called *proportional fairness*. The proportionally fair resource allocation solution to (4) is given by

$$\frac{w_r}{x_r} = q_r. \tag{5}$$

The network then allocates rate x_r to user r and charges q_r dollars per bit. From (5), the amount charged to user r per second is w_r, thus satisfying the original interpretation of w_r. Knowing that the network charges users in this manner, how might a user choose its bid w_r? Recall that user r's goal is to solve (4). Substituting from (5), the problem in (4) can be rewritten as

$$\max_{w_r \geq 0} U_r \left(\frac{w_r}{q_r}\right) - w_r. \tag{6}$$

Thus, the users' problem of selecting w can be viewed as a game, with each user's objective given by (6). Note that q_r is given by (5) and thus depends on all the w_r's. Depending upon the application, the game can be solved under one of two assumptions:

• *Price-Taking Users:* Under this assumption, users are assumed to take the price q_r as given, i.e., they do not attempt to infer the impact of their actions on the price. This is a reasonable assumption in a large network such as the Internet, where the impact of a single user on the link prices is negligible, and it is practically impossible for any user to infer the impact of its decisions on the prevailing price of the network resources. When the users are price taking, the socially optimal solution, i.e., the solution to the network utility maximization problem, coincides with the Nash equilibrium of the game. To see this, note that the solution to (6) is given by

$$\frac{1}{q_r} U_r' \left(\frac{w_r}{q_r}\right) - 1 = 0,$$

under the assumption that the utility function is differentiable and the solution is bounded away from zero. Using (5), this equation reduces to

$$U_r'(x_r) = q_r,$$

which maximizes the Lagrangian (3). It is not difficult to see that the complementary slackness equations in the Karush-Kuhn-Tucker conditions are satisfied since the constraints for (2) and the proportionally fair solution are the same. Thus, under the price-taking assumption, the equilibrium of the game solution is the same as the socially optimal solution provided the network computes q_r using the proportionally fair resource allocation formulation.

• *Strategic Users:* In networks where the number of users is small, it may be possible for each user to know the topology of the network, and thus, each user may be able to solve for the proportionally fair resource allocation if it has access to other users' bids. In other words, it may be possible to compute a Nash equilibrium by taking into account the impact of the w_r's on the q_r's. When the users are strategic, the socially optimal solution could be quite different from the Nash equilibrium. The ratio of the network utility under the socially optimal solution to the network utility under a Nash equilibrium is called the *price of anarchy*.

There is a rich literature associated with both interpretations of the network congestion game. In the case of price-taking users, much of the emphasis in the literature has been on designing distributed algorithms to achieve the socially optimal solution (Shakkottai and Srikant 2007). In the case of strategic users, the focus has been on characterizing the price of anarchy (Johari and Tsitsiklis 2004; Yang and Hajek 2007).

Summary and Future Directions

We have presented a number of applications which involve the interactions of selfish users over a network. For the resource allocation application, we have also described how simple mathematical models can be used to provide incentives for users to act in a socially optimal manner. In particular, we have shown that, under the reasonable price-taking assumption and an appropriate computation of link prices, selfish users automatically maximize network utility. In the case where the users are strategic, the goal is to characterize the price of anarchy.

Moving forward, two areas which require considerable further research are the following: (i) inter-ISP routing and (ii) spectrum sharing. The Internet is a fairly reliably network, and any unreliability often arises due to routing issues among ISPs. As mentioned in the introduction, peering arrangements between ISPs are necessary to make sure that ISPs carry each others' traffic and are appropriately compensated for it, either through reciprocal traffic-carrying agreements or actual monetary transfer. Thus, the policy that an ISP uses to route traffic may be governed by these peering agreements. The more complicated these policies are, the more chances there are for routing misconfigurations that lead to service interruptions. This interplay between policies and technology in the form of routing algorithms is an interesting topic for further study.

Cognitive radios and spectrum sharing are expected to be significant technological components of future wireless networks. Designing algorithms for selfish radios to share the available spectrum while respecting the rights of the primary user of the spectrum is a challenge that requires considerable further attention. This area of research requires one to combine sensing technologies to sense the presence of other users with game-theoretic models to ensure fair channel access to the secondary users, subject to the constraint that the primary user should not be affected by the presence of the secondary users.

Networked Control Systems: Architecture and Stability Issues

Linda Bushnell[1] and Hong Ye[2]
[1]Department of Electrical Engineering, University of Washington, Seattle, WA, USA
[2]The Mathworks, Inc., Natick, MA, USA

Abstract

When shared, band-limited, real-time communication networks are employed in a control system to exchange information between spatially distributed components, such as controllers, actuators, and sensors, it is categorized as a networked control system (NCS). The primary advantages of a NCS are reduced complexity and wiring, reduced design and implementation cost, ease of system maintenance and modification, and efficient data sharing. In addition, this unique architecture creates a way to connect the cyberspace to the physical space for remote operation of systems. The NCS architecture allows for performing more complex tasks, but also requires taking the network effects into account when designing control laws and stability conditions. In this entry, we review significant results on the architecture and stability analysis of a NCS. The results presented address communication network-induced challenges such as time delays, scheduling, and information packet dropouts.

Architecture; Networked control system; Stability

Introduction

From the washing machine, air conditioner, and microwave oven to the telephone, stereo, and automobile, embedded computers are present in the modern home. In a factory environment, there are thousands of networked smart sensors and actuators with embedded processors, working to complete a coordinated task. The trend in manufacturing plants, homes, buildings, aircraft, and automobiles is toward distributed networking. This trend can be inferred from many proposed or emerging network standards, such as controller area network (CAN) for automotive and industrial automation, BACnet for building automation, PROFIBUS and WorldFIP fieldbus for process control, and IEEE 802.11, and Bluetooth wireless standards for applications such as mobile sensor networks, HVAC systems, and unmanned aerial vehicles.

The traditional dedicated point-to-point wired connection in control systems has been successfully implemented in industry for decades. With the advance of communication network and hardware technologies, it is common to integrate the communication network into the control system to replace the dedicated point-to-point connection to achieve reduced weight and power, lower cost, simpler installation and maintenance, and higher reliability, to name a few advantages. For example, a typical new automobile has two controller area networks (CANs): a high-speed one in front of the firewall for the engine, transmission, and traction control and a low-speed one for locks, windows, and other devices (Johansson et al. 2005).

The conventional definition of a networked control system (NCS) is as follows: When a feedback control system is closed via a communication channel, which may be shared with other nodes outside the control system, then the control system is called a NCS. A NCS can also be described as a feedback control system where the control loops are closed through a real-time communication network.

Architecture of Networked Control Systems

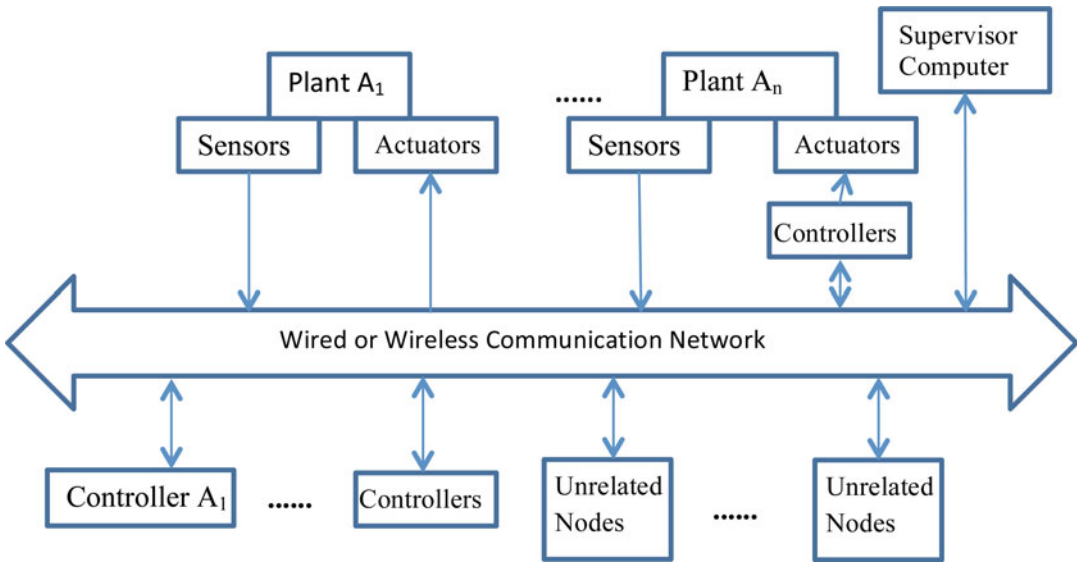
The architecture of a NCS consists of a band-limited, digital communication network physically and electronically integrated with a spatially distributed control system, operated on a given plant. Digital information, such as controller signals, actuator signals, sensor signals, and operator input, is transmitted via the network. The components connected by the network include all nodes of the control system, such as the supervisory (or "network owner") computer, controller software and hardware, actuators, and sensors. In this structure, the feedback control system's loops are closed over the shared communication network.

The communication network can be wired or wireless and may be shared with other unrelated nodes outside the control system. As illustrated in Fig. 1, the shared communication channel, which multiplexes signals from the sensors to the controllers and/or from the controllers to the actuators, serves many other uses besides control. Each of the system components directly connected to the network via a network interface is denoted a physical node. Besides the network interface, the sensors and actuator nodes are typically smart nodes with embedded microprocessors. Sometimes, the controller is colocated with the smart actuator. Several key issues make networked control systems distinct from traditional control systems (Hespanha et al. 2007; Yang 2006).

Band-Limited Channels

Bandwidth limitation of the shared communication channel requires that all nodes in the network must share (e.g., time sharing or frequency sharing, etc.) the common network resource without interfering with each other.

Sampling and Delays

In a NCS, the plant outputs are sampled by the sensors, which can convert continuous-time


Networked Control Systems: Architecture and Stability Issues, Fig. 1 A general networked control system (NCS) architecture

analog signals to digital signals; perform preprocessing, filtering, and encoding; and package the data signal so that it is ready for transmission. After winning the medium access control and being transmitted over the network, the package containing the sampled data signal arrives at the receiver side, which could be a controller or a smart actuator with a controller collocated with it. The receiver unpacks and decodes the signal. This process is quite different from the traditional periodic sampling in digital control. The overall delay between sampling and the eventual decoding of the transmitted packet at the receiver can be time varying and random due to both the network access delay (i.e., the time it takes for a shared network to accept the data) and the transmission delay (i.e., the time during which data are in transit inside the network). This also depends on the highly variable network conditions, such as congestion and channel quality. In some NCSs, the data transmitted are time stamped, which means that the receiver may have an estimate of the delay's duration and could take appropriate corrective action. Given the rapid advance of embedded computation and communication hardware technology today, the transmission delay in

many embedded systems can be neglected when compared with the magnitude of network access delay.

Packet Dropouts

It is possible in a NCS that a packet may be lost while it is in transit through the network. The packet that contains important sampling data or control signals may drop occasionally due to transmission errors of the physical network link, message collision, or node failures, to name a few. Overflow in queue or buffer can lead to network congestion and package loss. Thus, the use of queues is not favored by NCSs in general. Packet dropouts also happen if the receiver discards outdated arrivals that have long delays. Most network protocols are equipped with transmission-retry mechanisms, such as TCP, that guarantee the eventual delivery of packets. These protocols, unfortunately, are not appropriate for a NCS since the retransmission of old sensor data or calculated control signals is generally not very useful when new, time-critical data are available. Using selected old data for estimation or prediction is an exception, where old data may be packaged with the new

data in one packet. It is advantageous to discard the old, un-transmitted data and transmit a new packet if and when it becomes available. In this way, the controller always receives fresh data for its control calculation, and the actuator always executes the up-to-date command to control the plant.

Modeling Errors, Uncertainties, and Disturbances

In a distributed NCS, modeling errors, uncertainties, and disturbances always exist when using the mathematical model to describe the physical process. These factors may lead to a major impact on the overall system performance and cause failure in fulfilling the desired objectives. Wang and Hovakimyan (2013) proposed a reference model-based architecture to decouple the design of controller and communication schemes. A reference model is introduced in each subsystem as a bridge to build the connection between the real system and an ideal model, free of uncertainties. The closeness between the real system and the reference model is associated only with plant uncertainties, and the difference between the reference model and the ideal model is only in the communication constraints.

Stability of Networked Control Systems

The stability of a control system is often extremely important and is generally a safety requirement. Examples include the control of rockets, robots, airplanes, automobiles, or ships. Instability in any one of these systems can result in an unimaginable accident and loss of life. The stability of a general dynamical system with no input can be described with the Lyapunov stability criteria, which is stated as follows: A linear system is stable if its impulse response approaches zero as time approaches infinity or if every bounded input produces a bounded output.

When sensors, controllers, and actuators are not colocated and use a shared network to communicate, the feedback loop of a NCS is closed over the network. Network-induced,

variable delays, and packet dropouts can degrade the performance of a NCS. For example, the NCS may have a longer settling time or bigger overshoot in the step response. Furthermore, the NCS may become unstable when delays and/or packet dropouts exceed a certain range. Designers choosing to use a NCS architecture, however, are motivated not by performance but by cost, maintenance, and reliability gains.

Band-Limited Channels

Inspired by Shannon's results on the maximum bit rate that a communication channel can carry reliably, a significant research effort has been devoted to the problem of determining the minimum bit rate that is needed to stabilize a system through feedback over a finite capacity channel (Baillieul 1999; Nair and Evans 2000; Tatikonda and Mitter 2004; Wong and Brockett 1999; Baillieul and Antsaklis 2007). This has been solved exactly for linear plants, but only conservative results have been obtained for nonlinear plants. The data-rate theorem that quantifies a fundamental relationship between unstable physical systems and the rate at which information must be processed in order to stably control them was proved independently under a variety of assumptions. Minimum bit rate and quantization becomes especially important for networks designed to carry very small packets with little overhead, because encoding measurements or actuation signals with less bits can save network bandwidth.

Most of the NCS stability results presented here, however, are based on the observation that the channel can transmit a finite number of packets per unit of time (packet rate) and each packet can carry certain number of bits in the data field. The packets on a real-time control network typically are frequent and have small data segments compared to their headers. For example, a CAN II packet with a single 16-bit data sample has fixed 64 bits of overhead associated with identifier, control field, CRC, ACK field, and frame delimiter, resulting in 25 % utilization, and this utilization can never exceed 50 % (data field length is limited to 64 bits). Thus, the quantization effects imposed by the communication networks are generally ignored.

Network-Induced Delays

A significant number of results have attempted to characterize a maximum upper bound on the sampling or transmission interval for which stability of the NCS can be guaranteed. The upper bound is sometimes called the maximum allowable transfer interval (MATI) (Walsh 2001a). These results implicitly attempt to minimize the packet rate or schedule the traffic of the control network that is needed to stabilize a system through feedback. The general approach is to design the controller using established techniques, considering the network to be transparent, and then to analyze the effect of the network on closed-loop system performance and stability.

The NCS with a linear time-invariant (LTI) plant/controller pair and one-channel feedback (see Fig. 2) can be modeled by the following continuous-time system, where x includes the states of the plant and the controller, $x(t) = [x_p(t), x_c(t)]^T$:

$$\dot{x} = Ax + B\hat{y}, \quad y = C(x) \qquad (1)$$

$$\hat{y}(t) = \begin{cases} \hat{y}_{k-1}, t \in [t_k, t_k + \tau_k) \\ \hat{y}_k, t \in [t_k + \tau_k; t_{k+1}) \end{cases} \qquad (2)$$

The signal y is a vector of sensor measurements and $\hat{y}$ is the input to a continuous-time controller collocated with the actuators. Alternatively, $\hat{y}$ can be viewed as the input to the actuators and y as the desired control signal computed by a controller collocated with the sensors. The signal y(t) is sampled at times $\{t_k : k \in N\}$ and the samples $y(k) := y(t_k)$ are sent through the network. But the samples arrive at the destination after a (possibly variable) delay of τ_k, where we assume that the network delays are always smaller than one sampling interval. For periodic sampling and constant delays, a sufficient and necessary condition for exponential stability of the NCS (Eqs. 1 and 2) was derived (Zhang et al. 2001). By using the augmented state space model and based on the stability of nonlinear hybrid systems, they also proved the sufficient condition for stability of the NCS in the time-invariant case.

If we now assume the sampling intervals are constant and the computation and transmission delays are negligible, then the variable network access delays serve as the main source of delays in a NCS (Lin et al. 2003, 2005). Using average dwell time results for discrete switched systems, Zhai et al. (2002) provided conditions such that NCS stability is guaranteed. Also, the authors consider robust disturbance attenuation analysis for this class of NCSs.

When the network delay is not constant or when the signal y(t) is sampled in a nonperiodic fashion, the system (1) and (2) is not time invariant and one needs a Lyapunov-based argument to prove its stability. Zhang and Branicky (2001) derived the sufficient condition to ensure the NCS in Fig. 2 is exponentially stable. They also proposed a randomized algorithm to find the largest value of sampling interval for which stability can be guaranteed.

For a model-based NCS with state and output feedback, an explicit model of the plant is used to produce an estimate of the plant state behavior between transmission times (Montestruque and Antsaklis 2004). Sufficient conditions for Lyapunov stability are derived for a model-based NCS when the controller/actuator is updated with the sensor information at nonconstant time intervals. A NCS with transmission times that are driven by a stochastic process with identically independently distributed and Markov-chain-driven transmission times almost sure stability and mean-square sufficient conditions for stability are introduced. Onat et al. (2011) adapted above stability results to model-based predictive NCSs with realistic structure assumptions.
Networked Control Systems: Architecture and Stability Issues, Fig. 2 A NCS architecture with one-channel feedback (controller collocated with actuator)
Networked Control Systems: Architecture and Stability Issues, Fig. 3 A NCS architecture with two-channel feedback

Control Network Scheduler

In general a Multi-Input/Multi-Output (MIMO) NCS with two-channel feedback, both the sampled plant output and controller output are transmitted via a network (see Fig. 3). Because of the network, only the reported output y(t) is available to the controller and its prediction processes; similarly, only û(t) is available to the actuators on the plant. We label the network-induced error

$$e(t) := [\hat{y}(t), \hat{u}(t)]^T - [y(t), u(t)]^T$$

and the combined state of controller and plant $x(t) = [x_p(t), x_c(t)]^T$. The state of the entire NCS is given by $z(t) = [x(t), e(t)]^T$. Following this general approach, the controller is designed using established techniques without considering the presence of the network.

The behavior of the network-induced error $e(t)$ is mainly determined by the architecture of the NCS and the scheduling strategy. In the special case of one-package transmission, there is only one node transmitting data on the network; therefore, the entire vector $e(t)$ is set to zero at each transmission time. For multiple nodes transmitting measured outputs $y(t)$ and/or computed inputs $u(t)$, the transmission order of the nodes depends on the scheduling strategy chosen for the NCS. In other words, the scheduling strategy decides which components of $e(t)$ are set to zero at the transmission times.

Static and dynamic schedulers (a.k.a. protocols) are two main categories used in a NCS. When the network resource or transmission order are pre-allocated or determined before run-time,

it is called a static scheduler, such as round-robin scheduling. A dynamic scheduler determines the network allocation while the system runs. A novel dynamic network scheduler, try-once-discard (TOD) and several variations were introduced for wired and wireless NCSs (Walsh and Ye 2001; Ye et al. 2001). For linear and nonlinear NCSs with the new dynamic and commonly used static schedulers, an analytic proof of global exponential stability of a MIMO NCS was provided (Walsh 2001a; Walsh et al. 2001b). Simulation and experiment results showed that the dynamic schedulers outperform static schedulers in terms of NCS performance, e.g., a bigger MATI.

Nesic and Teel (2004a,b) generalize the above results by considering a nonlinear NCS with external disturbances and more general class of protocols (or schedulers). They considered a new class of Lyapunov uniformly globally asymptotically stable (UGAS) protocols in a NCS. It is shown that if the controller is designed without taking into account the network, it yields input-to-state stability (ISS) with respect to external disturbances (not necessarily with respect to the network-induced error), and then the same controller will achieve semi-global practical ISS for the NCS when implemented via the network with a Lyapunov UGAS protocol. Moreover, the ISS gain is preserved. The adjustable parameter with respect to which semi-global practical ISS is achieved is the MATI between transmission times. The authors also studied the input–output L_p stability of a NCS for a large class of network scheduling protocols. It is shown that polling, static protocols, and dynamic protocol such as TOD belong to this class. Results in Nesic and Teel (2004a) provide a unifying framework for generating new scheduling protocols that preserve L_p stability properties of the system, if a design parameter is chosen to be sufficiently small. The most general version of these results can also be used to model a NCS with data packet dropouts. The proof technique used is based on the small gain theorem and lends itself to an easy interpretation.

A framework for analyzing the stability of a general nonlinear NCS with disturbances in

the setting of L_p stability was provided by Tabbara et al. (2007). Their presentation provides sharper results for both gain and MATI than previously obtainable and details the property of uniformly persistently exciting scheduling protocols. This class of protocols was shown to lead to stability for high enough transmission rates. This was a natural property to demand, especially in the design of wireless scheduling protocols. The property is used directly in a novel proof technique based on the notions of vector comparison and (quasi)-monotone systems. Via simulations, analytical, and numerical comparison, it is verified that the uniform persistence of excitation property of protocols is, in some sense, the "finest" property that can be extracted from wireless scheduling protocols.

Delays and Packet Dropouts

Packet dropouts can be modeled as either stochastic or deterministic phenomena. For a one-channel feedback NCS, Zhang and Branicky (2001) consider a deterministic dropouts model, with packet dropouts occurring at an asymptotic rate. Stability conditions were studied for a NCS with deterministic and stochastic dropouts (Seiler and Sengupta 2005).

Sometimes, the NCS was characterized as a continuous-time delayed differential equation (DDE) with the time-varying delay $\tau(t)$. One important advantage is that the equations are still valid even when the delays exceed the sampling interval. Researchers successfully used the Lyapunov–Krasovskii (Yue et al. 2004) and the Razumikhin theorems (Yu et al. 2004) to study the stability of a NCS that is modeled as DDEs.

Summary and Future Directions

This article introduced the concept of a networked control system and its general architecture. Several key issues specific to a NCS, such as band-limited channels, network-induced delays, and information packet dropouts, were explained. The stability condition of a NCS with various network effects was discussed with several common modeling techniques.

In terms of future directions, there has been significant effort in analyzing networked control systems with variable sampling rate, but most results investigate the stability for a given worst-case interval between consecutive sampling times, leading to conservative results. An open area of research would be to look at methods that take into account a stochastic characterization for the inter-sampling times. Substantial work has also been devoted to determining the stability of a NCS, as described in this article. Possible open areas of research would be to consider design issues related to the joint stability and performance of the system. The design and development of controllers for a NCS is also an open area of research. In designing a controller for a NCS, one has to take into account the challenges introduced by the communication network. Only afterward can analysis of the whole system take place.

[2]Department of Electronics Engineering, Federal University of Minas Gerais, Belo Horizonte, Brazil

Abstract

This entry discusses optimal estimation and control for lossy networks. Conditions for stability are provided both for two-link and multiple-link networks. The online adaptation of network resources (controlled communication) is also considered.

Keywords

Automatic control; Communication networks; Controlled communication; Estimation; Networked control systems; Stability

Introduction

Network Control Systems (NCSs) are spatially distributed systems in which the communication between sensors, actuators, and controllers

occurs through a shared band-limited digital communication network. In this entry, we consider the problem of estimation and control over such networks.

A significant difference between NCSs and standard digital control is the possibility that data may be lost while in transit through the network. Typically, *packet dropouts* result from transmission errors in physical network links (which is far more common in wireless than in wired networks) or from buffer overflows due to congestion. Long transmission delays sometimes result in packet reordering, which essentially amounts to a packet dropout if the receiver discards "outdated" arrivals. Reliable transmission protocols, such as TCP, guarantee the eventual delivery of packets. However, these protocols are not appropriate for NCSs since the retransmission of old data is generally not useful. Another important difference between NCSs and standard digital control systems is that, due to the nature of network traffic, delays in the control loop may be time varying and nondeterministic.

In this entry, we concentrate on the problem of control and estimation in the presence of packet losses, leaving other important features of NCSs (such as quantization and random delays) to be addressed in other entries of this encyclopedia. Consequently, we assume that the network can be viewed as a channel that can carry real numbers without distortion, but that some of the messages may be lost. This network model is appropriate when the number of bits in each data packet is sufficiently large so that quantization effects can be ignored, but packet dropouts cannot. For more general channel models, see, for example, Imer and Basar (2005).

This entry also does not address network transmission delays explicitly. In general, network delays have two components: one that is due to the time spent transmitting packets and another due to the time packets wait in buffers waiting to be transmitted. Delays due to packet transmission present little variation and may be modeled as constants. For control design purposes, these delays may be incorporated into the plant model. Delays due to buffering depend on the network

traffic and are typically random; they can be analyzed using the techniques developed in Antunes et al. (2012).

Notation and Basic Definitions. Throughout the entry, $\mathbb{R}$ stands for real numbers and $\mathbb{N}$ for nonnegative integers. For a given matrix $A \in \mathbb{R}^{n \times n}$ and vector $x \in \mathbb{R}^n$, $\|x\| := \sqrt{x'x}$ denotes the Euclidean norm of x, and $\lambda(A)$ the set of eigenvalues of A. Random variables are generally denoted in boldface. For a random variable $\mathbf{y}$, $\mathrm{E}[\mathbf{y}]$ stands for the expectation of $\mathbf{y}$.

Two-Link Networks

Here, we consider a control/estimation problem when all network effects can be modeled using two erasure channels: one from the sensor to the controller and the other from the controller to the actuator (see Fig. 1).

We restrict our attention to a linear time-invariant (LTI) plant with intermittent observation and control packets:

$$\mathbf{x}_{k+1} = A\mathbf{x}_k + \nu_k B \mathbf{u}_k + \mathbf{w}_k, \qquad (1a)$$

$$\mathbf{y}_k = \theta_k C \mathbf{x}_k + \mathbf{v}_k, \qquad (1b)$$

$\forall k \in \mathbb{N}, \mathbf{x}_k, \mathbf{w}_k \in \mathbb{R}^n, \mathbf{y}_k, \mathbf{v}_k \in \mathbb{R}^p$, where $(\mathbf{x}_0, \mathbf{w}_k, \mathbf{v}_k)$ are mutually independent, zero-mean Gaussian with covariance matrices (P_0, R_w, R_v), and $\theta_k, \nu_k \in \{0, 1\}$ are i.i.d. Bernoulli random variables with $\Pr\{\theta_k = 1\} = \bar{\theta}$ and $\Pr\{\nu_k = 1\} = \bar{\nu}$. The variable θ_k models the packet loss between sensor and controller, whereas ν_k models the packet loss between controller and actuator. When there is a packet drop from controller
Networked Control Systems: Estimation and Control Over Lossy Networks, Fig. 1 Control system with two network links

to actuator, we set the actuator's output to zero. Different strategies, such as holding the control input, could still be modeled using (1) by augmenting of the state vector.

The information available to the controller up to time k is given by the information set:

$$\mathcal{I}_k = \{P_0\} \cup \{\mathbf{y}_\ell, \theta_\ell : \ell \leq k\} \cup \{\nu_\ell : \ell \leq k - 1\}.$$

Here, we make an important assumption that acknowledgment packets from the actuator are always received by the controller so that $\nu_\ell, \ell \leq k - 1$ is available at time k to the remote estimator.

Optimal Estimation with Remote Computation

The optimal mean-square estimate of $\mathbf{x}_k$, given the information known to the remote estimator at time k, is given by

$$\hat{\mathbf{x}}_{k|k} := \mathrm{E}[\mathbf{x}_k | \mathcal{I}_k].$$

This estimate can be computed recursively using the following time-varying Kalman filter (TVKF) (Sinopoli et al. 2004):

$$\hat{\mathbf{x}}_{0|-1} = 0, \tag{2a}$$

$$\hat{\mathbf{x}}_{k|k} = \hat{\mathbf{x}}_{k|k-1} + \theta_k F_k (\mathbf{y}_k - C\hat{\mathbf{x}}_{k|k-1}), \tag{2b}$$

$$\hat{\mathbf{x}}_{k+1|k} = A\hat{\mathbf{x}}_{k|k} + \nu_k B\mathbf{u}_k, \tag{2c}$$

with the gain matrix F_k calculated recursively as follows

$$F_k = P_k C'(CP_k C' + R_v)^{-1},$$

$$P_{k+1} = AP_k A' + R_w - \theta_k AF_k(CP_k C' + R_v) F_k' A'.$$

Each P_k corresponds to the estimation error covariance matrix

$$P_k = \mathrm{E}\left[(\mathbf{x}_k - \hat{\mathbf{x}}_{k|k-1})(\mathbf{x}_k - \hat{\mathbf{x}}_{k|k-1})'\right].$$

For this estimator, there exists a critical value θ_c for the dropout rate $\bar{\theta}$, above which the estimation error covariance becomes unbounded:

Theorem 1 (Sinopoli et al. 2004) *Assume that $\left(A, R_w^{1/2}\right)$ is controllable, (A, C) is observable, and A is unstable. Then there exists a critical value $\theta_c \in (0, 1]$ such that*

$$\mathrm{E}[P_k] \leq M, \forall k \in \mathbb{N} \Leftrightarrow \bar{\theta} \geq \theta_c$$

where M is a positive definite matrix that may depend on P_0. Furthermore, the critical value θ_c satisfies $\theta_{\min} \leq \theta_c \leq \theta_{\max}$, where the lower bound is given by

$$\theta_{\min} = 1 - \frac{1}{(\max\{|\lambda(A)|\})^2}, \tag{3}$$

and the upper bound is given by the solution to the following (quasi-convex) optimization problem:

$$\theta_{\max} = \min\{\theta \geq 0 : \Psi_\theta(Y, Z) > 0,$$
$$0 \leq Y \leq I \text{ for some } Y, Z\},$$

where

$$\Psi_\theta(Y, Z) =$$

$$\begin{bmatrix} Y & \sqrt{\theta}(YA + ZC) & \sqrt{1-\theta}YA \\ \sqrt{\theta}(A'Y + C'Z') & Y & 0 \\ \sqrt{1-\theta}A'Y & 0 & Y \end{bmatrix}.$$

Remark 1 In some special cases, the upper bound in (3) is tight in the sense that $\theta_c - \theta_{\min}$. The largest class of systems known for which this occurs is that of *nondegenerate systems* defined in Mo and Sinopoli (2012). Examples of systems in this class include (1) those for which the matrix C is invertible and (2) those with a detectable pair (A, C) and such that the matrix A is diagonalizable with unstable eigenvalues having distinct absolute values.

Optimal Control with Remote Computation

From a control perspective, one may also be interested in finding control sequences $\mathbf{u}^N = \{\mathbf{u}_1, \ldots, \mathbf{u}_{N-1}\}$, as functions of the information set $\mathcal{I}_N$, which minimize cost functions of the form

$$J = \lim_{N \to \infty} \frac{1}{N} \mathrm{E} \left[\sum_{k=0}^{N-1} (\mathbf{x}_k' W \mathbf{x}_k + \nu_k \mathbf{u}_k' U \mathbf{u}_k) | \mathcal{I}_k \right].$$

Theorem 2 (Schenato et al. 2007) *Assume that (A, B) and $(A, R_w^{1/2})$ are controllable, (A, C) and $(A, W^{1/2})$ are observable, and A is unstable. Then, finite control costs J are achievable if and only if $\bar{\theta} > \theta_c$ and $\bar{\nu} > \nu_c$, where the critical value ν_c is given by the (quasi-convex) optimization problem*

$$\nu_c = \min\{\nu \geq 0 : \Psi_\nu(Y, Z) > 0, \\ 0 \leq Y \leq I \text{ for some } Y, Z\},$$

where

$$\Psi_\nu(Y, Z) =$$
$$\begin{bmatrix} Y & Y & \sqrt{\nu} Z U^{1/2} & \sqrt{\nu}(YA' + ZB') & \sqrt{1-\nu}YA' \\ Y & W^{-1} & 0 & 0 & 0 \\ \sqrt{\nu}U^{1/2}Z' & 0 & I & 0 & 0 \\ \sqrt{\nu}(AY + BZ') & 0 & 0 & Y & 0 \\ \sqrt{1-\nu}AY & 0 & 0 & 0 & Y \end{bmatrix}.$$

Moreover, under the above conditions, the separation principle holds in the sense that the optimal control is given by

$$\mathbf{u}_k = -(B'SB + U)^{-1} B'SA\hat{\mathbf{x}}_{k|k},$$

where $\hat{\mathbf{x}}_{k|k}$ is an optimal state estimate given by (2) and the matrix S is the solution to the modified algebraic Riccati (MARE) equation

$$S = A'SA + W - \bar{\nu}A'SB(B'SB + U)^{-1}B'SA.$$

Solutions to the MARE may be obtained iteratively when $\bar{\nu} > \nu_c$.

Estimation with Local Computation

To reduce the gap between the bounds $\theta_{\min}$ and $\theta_{\max}$ on the critical value of the drop probability in Theorem 1 and to allow for larger probabilities of drop, one may choose to compute state estimates at the sensor and transmit those to the controller/actuator. This scheme is motivated by the growing number of *smart sensors* with embedded processing units that are capable of local computation. For the LTI plant

$$\mathbf{x}_{k+1} = A\mathbf{x}_k + B\mathbf{u}_k + \mathbf{w}_k,$$
$$\mathbf{y}_k = C\mathbf{x}_k + \mathbf{v}_k,$$

the smart sensor can compute locally an optimal state estimate using a standard stationary Kalman filter and transmits this estimate to the controller. We model packet dropouts as before using the process θ_k and assume that the process θ_k is known to the smart sensor by means of an perfect acknowledgment mechanism. This allows the sensor to know $\mathbf{u}_k$ exactly and to use it in the Kalman filter.

Let $\tilde{\mathbf{x}}_{k|k} = \mathrm{E}[\mathbf{x}_k | \mathbf{y}_\ell, \theta_\ell, \ell \leq k]$ denote the local estimates transmitted by the sensor. Using the messages successfully received up to time k, the remote estimator computes the optimal estimate

$$\hat{\mathbf{x}}_{k|k-1} = \mathrm{E}[\mathbf{x}_k | \theta_\ell, \tilde{\mathbf{x}}_{\ell|\ell}, \ell \leq k-1].$$

recursively by

$$\hat{\mathbf{x}}_{0|-1} = 0,$$
$$\hat{\mathbf{x}}_{k|k} = (1 - \theta_k)\hat{\mathbf{x}}_{k|k-1} + \theta_k\tilde{\mathbf{x}}_{k|k}, \quad k \in \mathbb{N},$$
$$\hat{\mathbf{x}}_{k+1|k} = A\hat{\mathbf{x}}_{k|k} + B\mathbf{u}_k$$

N

Notice that now we are applying the (TVKF) to estimate $\tilde{\mathbf{x}}_k$, which is fully observable. Since $\theta_{\min}$ and $\theta_{\max}$ in Theorem 2 are equal for fully observable processes (Schenato et al. 2007), the local computation scheme grants a minimal critical value θ_c as stated in the theorem below.

Theorem 3 *Assume that $(A, R_w^{1/2})$ is controllable, (A, C) is* OBSERVABLE*, and A is unstable. Then the critical value θ_c is given by $\theta_{\min}$ in* (3)*, i.e.,*

$$\mathrm{E}[P_k] \leq M, \forall k \in \mathbb{N} \quad \Leftrightarrow \quad \bar{\theta} \geq \theta_{\min}$$

where M is a positive definite matrix that may depend on P_0.

Drops in the Acknowledgement Packets

When there are drops in the acknowledgment channel from the actuator to the controller, the controller does not always know ν_k, and therefore, it might not always have access to the control inputs that are actually applied to the plant. In this case, the posterior state probability becomes a Gaussian mixture distribution with infinitely many components, and the separation principle no longer holds (Schenato et al. 2007). This makes the estimation and control problems computationally more difficult, and, due to the smaller information set, some performance degradation in the control performance should be expected. For this reason, it is generally a good design choice to keep controller and actuator collocated when drops in the acknowledgment channels are significant.

Buffering

As an alternative to the approach described in section "Estimation with Local Computation" to use local computation at a smart sensor to allow for larger probabilities of drop, the designer may also consider the transmission of a sequence of previous measurements $\mathbf{y}_k, \mathbf{y}_{k-1}, \ldots, \mathbf{y}_{k-N}$ in each packet. This approach is motivated by the fact that often data packets can carry much more than one vector of measured outputs. When N is reasonably large, one should expect similar estimation/control performances as in

the approach described in section "Estimation with Local Computation", but with a reduced computational effort at the sensor.

Analogously, an improvement to zeroing or simply holding the control input in case of packet drops between controller and actuator is for the controller to transmit a control sequence $\mathbf{u}_k, \mathbf{u}_{k+1}, \ldots, \mathbf{u}_{k+N}$ that contains not only the control $\mathbf{u}_k$ to be used at the current time instant but also a few future controls $\mathbf{u}_{k+1}, \mathbf{u}_{k+2}, \ldots, \mathbf{u}_{k+N}$. In the case of packet drops between controller and actuator, the actuator can use previously received "future" control inputs in lieu of the one contained in the lost packet. The sequence of future control inputs may be obtained, e.g., by an optimal receding horizon control strategy (Gupta et al. 2006).

Estimation with Markovian Drops

When θ_k is a Markov process, we no longer have a separation principle, and the optimal controller may depend on the drops sequence. Yet, optimal state estimates are obtained using the same TVKF presented earlier. Below, we give conditions for the stability of the error covariance when drops are governed by the Gilbert-Elliot model: $\Pr\{\theta_{k+1} = j | \theta_k = i\} = p_{ij}, i, j \in \{0, 1\}$.

Theorem 4 (Mo and Sinopoli 2012) *Assume that $(A, R_w^{1/2})$ is controllable, A is unstable, and the system given by the pair (A, C) is nondegenerate as discussed in Remark 1. Moreover, suppose that the transition probabilities for the Gilbert-Elliot model satisfy $p_{01}; p_{10} > 0$. Then the expected error covariance $\mathrm{E}[P_k]$ is uniformly bounded if*

$$p_{01} > \theta_{\min}$$

and it is unbounded for some initial condition if $p_{01} < \theta_{\min}$.

Networks with Multiple Links

We now consider feedback loops that are closed over a network of communication links, each of which drops packets according to a Bernoulli

process. The sensor communicates with a controller across the network, and we assume that controller and actuator are collocated. The network may be represented by a graph $\mathcal{G}$ with nodes in the set $\mathcal{V}$ and edges in the set $\mathcal{E}$, where edges are drawn between two communicating nodes. We denote by p_{ij} the probability of a drop when node i transmits to node j. Drops are assumed to be independent across links and time.

To maximize robustness with respect to drops, sensors use a Kalman filter to compute an optimal estimate for the state of the process based on their measurements and transmit this estimate across the network. When the sensors do not have access to the process input, they can take advantage of the linearity of the Kalman filter: as the output of a Kalman filter is the sum of a term due to measurements with another term due to control inputs, sensors may compute only the contribution due to measurements and transmit it to the controller, which can subsequently add the contribution due to the control inputs. This guarantees that optimal state estimates can still be computed at the control node, even when the sensors do not know the control input (Gupta et al. 2009).

The communication in the network goes as follows. Sensors time stamp their estimates and broadcast them to all nodes in their communication ranges. After receiving information from their neighbors, nodes compare time stamps and keep only the most recent estimates. These estimates are broadcasted to all neighboring nodes. When the controller receives new information, the optimal Kalman estimate is reconstructed, taking into account the total transmission delay (learned from the packet time stamps), and a standard LQG control can be used (Gupta et al. 2009).

To determine whether or not this procedure results in a stable closed loop, one defines a *cut* $\mathcal{C} = (\mathcal{S}, \mathcal{T})$ to be a partition of the node set $\mathcal{V}$ such that the sensor node is in $\mathcal{S}$ and the controller node is in $\mathcal{T}$. The cut-set is then defined as the set of edges $(i, j) \in \mathcal{E}$ such that $i \in \mathcal{S}$ and $j \in \mathcal{T}$, i.e., the set of edges that connect the sets $\mathcal{S}$ and $\mathcal{T}$. The *max-cut probability* is then defined as

$$p_{\text{max-cut}} = \max_{\text{all cuts}(\mathcal{S},\mathcal{T})} \prod_{(i,j)\in\mathcal{S}\times\mathcal{T}} p_{ij}.$$

The above maximization can be rewritten as a minimization over the sums of $-\log p_{ij}$, which leads to a linear program known as the minimum cut problem in network optimization theory (Cook 1995).

Theorem 5 (Gupta et al. 2009) *Assume that* $R_w, R_v > 0$, *that* (A, B) *is stabilizable, that* (A, C) *is observable, and that A is unstable. Then the control and communication policy described above is optimal for quadratic costs, and the expected state covariance is bounded if and only if*

$$p_{\text{max-cut}} \cdot (\max\{|\lambda(A)|\})^2 < 1.$$

Estimation with Controlled Communication

To actively reduce network traffic and power consumption, sensor measurements may not be sent to the remote estimator at every time step. In addition, one may have the ability to somewhat control the probability of packet drops by varying the transmit power or by transmitting copies of the same message through multiple channel realizations. This is known as *controlled communication*, and it allows the designer to establish a trade-off between communication and estimation performance.

We consider the local estimation scenario described in section "Estimation with Local Computation" with the difference that the Bernoulli drops are now modulated as follows

$$\theta_k = \begin{cases} 1 & \text{with prob. } \Lambda_k \\ 0 & \text{with prob. } 1 - \Lambda_k \end{cases}$$

where the sensor is free to choose $\Lambda_k \in [0, p_{\text{max}}]$ as a function of the information available up to time k. With its choice, the sensor incurs on a communication cost $c(\Lambda_k)$ at time k, where $c(\cdot)$ is some increasing function that may represent, for example, the energy needed in order to transmit with a probability of drop equal to Λ_k. Note

that transmission scheduling, where Λ_k is either 0 or $p_{\max}$, is a special case of this framework.

In order to choose Λ_k, the sensor considers the estimation error $\tilde{\mathbf{e}}_k := \tilde{\mathbf{x}}_{k|k} - \hat{\mathbf{x}}_{k|k-1}$ between the local and the remote estimators. This error evolves according to

$$\tilde{\mathbf{e}}_{k+1} = \begin{cases} \mathbf{d}_k & \text{with prob. } \Lambda_k \\ A\tilde{\mathbf{e}}_k + \mathbf{d}_k & \text{with prob. } 1 - \Lambda_k \end{cases}$$

where $\mathbf{d}_k$ is the innovations process arising from the standard Kalman filter in the smart sensor.

Our objective is to find a "communication policy" that minimizes the long-term average cost

$$\tilde{J} := \lim_{K\to\infty} \frac{1}{K}\mathrm{E}\left[\sum_{k=0}^{K-1}\|\tilde{\mathbf{e}}_k\|^2 + \lambda c(\Lambda_k)\right],$$
$$\lambda > 0, \tag{4}$$

which penalizes a linear combination of the remote estimation error variance $\mathrm{E}\left[\|\tilde{\mathbf{e}}_k\|^2\right]$ and the average communication cost $\mathrm{E}[c(\Lambda_k)]$. In this context, a *communication policy* should be understood as a rule that selects Λ_k as a function of the information available to the sensor.

When

$$(1 - p_{\max})\max\{|\lambda(A)|\}^2 < 1,$$

there exists an optimal communication policy that chooses Λ_k as a function of $\tilde{e}_k$, which may be computed via dynamic programming and value iteration (Mesquita et al. 2012). While this procedure can be computationally difficult, it is often possible to obtain suboptimal but reasonable performance with rollout policies such as the following one:

$$\Lambda_k = \arg\min_{\Lambda \in [0, p_{\max}]}[(p_{\max} - \Lambda)\tilde{\mathbf{e}}_k' A' H A \tilde{\mathbf{e}}_k$$
$$+ \lambda c(\Lambda)] \tag{5}$$

where H is the positive semidefinite solution to the Lyapunov equation $(1 - p_{\max})A'HA - H = -I$ (Mesquita et al. 2012).

When computing $\tilde{\mathbf{e}}_k$ and Λ_k in (5) is computationally too costly for the sensor, one may prefer to make Λ_k a function of the number of consecutive dropped packets ℓ_k. In this case, minimizing $\tilde{J}$ in (4) is equivalent to minimizing the cost

$$\bar{J} := \lim_{K\to\infty} \frac{1}{K}\mathrm{E}\left[\sum_{k=0}^{K-1}\text{trace}\left(\Sigma_{\ell_k}\right) + \lambda c(\Lambda_k)\right],$$

where

$$\Sigma_\ell := \sum_{m=0}^{\ell} A'^m R_w A^m.$$

Since ℓ_k belongs to a countable set, one can very efficiently solve this optimization using dynamic programming (Mesquita et al. 2012).

Summary and Future Directions

Most positive results in the subject rely on the assumption of perfect acknowledgments and on actuators and controllers being collocated. Future research should address ways of circumventing these assumptions.

Networked Systems

Jorge Cortés

Department of Mechanical and Aerospace Engineering, University of California, San Diego, La Jolla, CA, USA

Abstract

This entry provides a brief overview on networked systems from a systems and control perspective. We pay special attention to the nature of the interactions among agents; the critical role played by information sharing, dissemination, and aggregation; and the distributed control paradigm to engineer the behavior of networked systems.

Keywords

Autonomous networks; Cooperative control; Multi-agent systems; Swarms

Introduction

Networked systems appear in numerous scientific and engineering domains, including communication networks (Toh 2001), multi-robot networks (Arkin 1998; Balch and Parker 2002), sensor networks (Santi 2005; Schenato et al. 2007), water irrigation networks (Cantoni et al. 2007), power and electrical networks (Chow 1982; Chiang et al. 1995; Dörfler et al. 2013), camera networks (Song et al. 2011), transportation networks (Ahuja et al. 1993), social networks (Jackson 2010), and chemical and biological networks (Kuramoto 1984; Strogatz 2003). Their applications are pervasive, ranging from environmental monitoring, ocean sampling, and marine energy systems, through search and rescue missions, high-stress deployment in disaster recovery, health monitoring of critical infrastructure to science imaging, the smart grid, and cybersecurity.

The rich nature of networked systems makes it difficult to provide a definition that, at the same time, is comprehensive enough to capture their variety and simple enough to be expressive of their main features. With this in mind, we loosely define a networked system as a "system of systems," i.e., a collection of agents that interact with each other. These groups might be heterogeneous, composed by human, biological, or engineered agents possessing different capabilities regarding mobility, sensing, actuation, communication, and computation. Individuals may have objectives of their own or may share a common objective with others – which in turn might be adversarial with respect to another subset of agents.

In a networked system, the evolutions of the states of individual agents are coupled. Coupling might be the result of the physical interconnection among the agents, the consequence of the implementation of coordination algorithms where agents use information about each other, or a combination of both. There is diversity too in the nature of agents themselves and the interactions among them, which might be cooperative, adversarial, or belong to the rich range between the two. Due to changes in the state of the agents, the network, or the environment, interactions among

agents may be changing and dynamic. Such interactions may be structured across different layers, which themselves might be organized in a hierarchical fashion. Networked systems may also interact with external entities that specify high-level commands that trickle down through the system all the way to the agent level.

A defining characteristic of a networked system is the fact that information, understood in a broad sense, is sparse and distributed across the agents. As such, different individuals have access to information of varying degrees of quality. As part of the operation of the networked system, mechanisms are in place to share, transmit, and/or aggregate this information. Some information may be disseminated throughout the whole network or, in some cases, all information can be made centrally available at a reasonable cost. In other scenarios, however, the latter might turn out to be too costly, unfeasible, or undesirable because of privacy and security considerations. Individual agents are the basic unit for decision making, but decisions might be made from intermediate levels of the networked system all the way to a central planner. The combination of information availability and decision-making capabilities gives rise to an ample spectrum of possibilities between the centralized control paradigm, where all information is available at a central planner who makes the decisions, and the fully distributed control paradigm, where individual agents only have access to the information shared by their neighbors in addition to their own.

Perspective from Systems and Control

There are many aspects that come into play when dealing with networked systems regarding computation, processing, sensing, communication, planning, motion control, and decision making. This complexity makes their study challenging and fascinating and explains the interest that, with different emphases, they generate in a large number of disciplines. In biology, scientists analyze synchronization phenomena and self-organized swarming behavior in groups with

distributed agent-to-agent interactions (Okubo 1986; Parrish et al. 2002; Conradt and Roper 2003; Couzin et al. 2005). In robotics, engineers design algorithmic solutions to help multivehicle networks and embedded systems coordinate their actions and perform challenging spatially distributed tasks (Arkin 1998; Committee on Networked Systems of Embedded Computers 2001; Balch and Parker 2002; Howard et al. 2006; Kumar et al. 2008). Graph theorists and applied mathematicians study the role played by the interconnection among agents in the emergence of phase transition phenomena (Bollobás 2001; Meester and Roy 2008; Chung 2010). This interest is also shared in communication and information theory, where researchers strive to design efficient communication protocols and examine the effect of topology control on group connectivity and information dissemination (Zhao and Guibas 2004; Giridhar and Kumar 2005; Lloyd et al. 2005; Santi 2005; Franceschetti and Meester 2007). Game theorists study the gap between the performance achieved by global, network-wide optimizers and the configurations that result from selfish agents interacting locally in social and economic systems (Roughgarden 2005; Nisan et al. 2007; Easley and Kleinberg 2010; Marden and Shamma 2013). In mechanism design, researchers seek to align the objectives of individual self-interested agents with the overall goal of the network. Static and mobile networked systems and their applications to the study of natural phenomena in oceans (Paley et al. 2008; Graham and Cortés 2012; Zhang and Leonard 2010; Das et al. 2012; Ouimet and Cortés 2013), rivers (Ru and Martínez 2013; Tinka et al. 2013), and the environment (DeVries and Paley 2012) also raise exciting challenges in estimation theory, computational geometry, and spatial statistics.

The field of systems and control brings a comprehensive approach to the modeling, analysis, and design of networked systems. Emphasis is put on the understanding of the general principles that explain how specific collective behaviors emerge from basic interactions; the establishment of models, abstractions, and tools that allow us to reason rigorously about complex

interconnected systems; and the development of systematic methodologies that help engineer their behavior. The ultimate goal is to establish a science for integrating individual components into complex, self-organizing networks with predictable behavior. To realize the "power of many" and expand the realm of what is possible to achieve beyond the individual agent capabilities, special care is taken to obtain precise guarantees on the stability properties of coordination algorithms, understand the conditions and constraints under which they work, and characterize their performance and robustness against a variety of disturbances and disruptions.

Research Issues – and How the Entries in the Encyclopedia Address Them

Given the key role played by agent-to-agent interactions in networked systems, the Encyclopedia entries ▶ Graphs for Modeling Networked Interactions and ▶ Dynamic Graphs, Connectivity of deal with how their nature and effect can be modeled through graphs. This includes diverse aspects such as deterministic and stochastic interactions, static and dynamic graphs, state-dependent and time-dependent neighboring relationships, and connectivity. The importance of maintaining a certain level of coordination and consistency across the networked system is manifested in the various entries that deal with coordination tasks that are, in some way or another, related to some form of agreement. These include consensus (▶ Averaging Algorithms and Consensus), formation control (▶ Vehicular Chains), cohesiveness, flocking (▶ Flocking in Networked Systems), synchronization (▶ Oscillator Synchronization), and distributed optimization (▶ Distributed Optimization). A great deal of work (e.g., see ▶ Optimal Deployment and Spatial Coverage and ▶ Multi-vehicle Routing), is also devoted to the design of cooperative strategies that achieve spatially distributed tasks such as optimal coverage, space partitioning, vehicle routing, and servicing. These entries explore the optimal placement of agents,

the optimal tuning of sensors, and the distributed optimization of network resources. The entry ▶ Estimation and Control over Networks explores the impact that communication channels may have on the execution of estimation and control tasks over networks of sensors and actuators. A strong point of commonality among the contributions is the precise characterization of the scalability of coordination algorithms, together with the rigorous analysis of their correctness and stability properties. Another focal point is the analysis of the performance gap between centralized and distributed approaches in regard to the ultimate network objective.

Further information about other relevant aspects of networked systems can be found throughout this Encyclopedia. Among these, we highlight the synthesis of cooperative strategies for data fusion, distributed estimation, and adaptive sampling, the analysis of the network operation under communication constraints (e.g., limited bandwidth, message drops, delays, and quantization), the treatment of game-theoretic scenarios that involve interactions among multiple players and where security concerns might be involved, distributed model predictive control, and the handling of uncertainty, imprecise information, and events via discrete-event systems and triggered control.

Summary and Future Directions

In conclusion, this entry has illustrated ways in which systems and control can help us design and analyze networked systems. We have focused on the role that information and agent interconnection play in shaping their behavior. We have also made emphasis on the increasingly rich set of methods and techniques that allow to provide correctness and performance guarantees. The field of networked systems is vast and the amount of work impossible to survey in this brief entry. The reader is invited to further explore additional topics beyond the ones mentioned here. The monographs (Ren and Beard 2008; Bullo et al. 2009; Mesbahi and Egerstedt 2010; Alpcan and Başar 2010) and edited

volumes (Kumar et al. 2004; Shamma 2008; Saligrama 2008), and manuscripts (Olfati-Saber et al. 2007; Baillieul and Antsaklis 2007; Leonard et al. 2007; Kim and Kumar 2012), together with the references provided in the Encyclopedia entries mentioned above, are a good starting point to undertake this enjoyable effort. Given the big impact that networked systems have, and will continue to have, in our society, from energy and transportation, through human interaction and healthcare, to biology and the environment, there is no doubt that the coming years will witness the development of more tools, abstractions, and models that allow to reason rigorously about intelligent networks and for techniques that help design truly autonomous and adaptive networks.

Neural Control and Approximate Dynamic Programming

Frank L. Lewis[1] and Kyriakos G. Vamvoudakis[2]
[1]Arlington Research Institute, University of Texas, Fort Worth, TX, USA
[2]Center for Control, Dynamical Systems and Computation (CCDC), University of California, Santa Barbara, CA, USA

Abstract

There has been great interest recently in "universal model-free controllers" that do not need a mathematical model of the controlled plant, but mimic the functions of biological processes to learn about the systems they are controlling online, so that performance improves automatically. Neural network (NN) control has had two major thrusts: approximate dynamic programming, which uses NN to approximately solve the optimal control problem, and NN in closed-loop feedback control.

Keywords

Adaptive control; Learning systems; Neural networks; Optimal control; Reinforcement learning

Neural Feedback Control

The objective is to design NN feedback controllers that cause a system to follow, or track,

a prescribed trajectory or path. Consider the dynamics of an n-link robot manipulator

$$M(q)\ddot{q} + V_m(q, \dot{q})\dot{q} + G(q) + F(\dot{q}) + \tau_d = \tau \tag{1}$$

with $q(t) \in \mathbb{R}^n$ the joint variable vector, $M(q)$ an inertia matrix, V_m a centripetal/coriolis matrix, $G(q)$ a gravity vector, and $F(\cdot)$ representing friction terms. Bounded unknown disturbances and modeling errors are denoted by τ_d and the control input torque is $\tau(t)$. The sliding mode control approach (Slotine and Li 1987) can be generalized to NN control systems. Given a desired trajectory, $q_d \in \mathbb{R}^n$ define the tracking error $e(t) = q_d(t) - q(t)$ and the sliding variable error $r = \dot{e} + \lambda e$ with $\lambda = \lambda^T > 0$. Define the nonlinear robot function,

$$f(x) = M(q)(\ddot{q}_d + \lambda \dot{e}) + V_m(q, \dot{q})(\dot{q}_d + \lambda e) \\ + G(q) + F(\dot{q})$$

with the known vector $x(t)$ of measured signals is selected as, $x = \begin{bmatrix} e^T & \dot{e}^T & q_d^T & \dot{q}_d^T & \ddot{q}_d^T \end{bmatrix}$.

NN Controller for Continuous-Time Systems

The NN controller is designed based on *functional approximation properties* of NN as shown in Lewis et al. (1999). Thus, assume that $f(x)$ can be approximated by $\hat{f}(x) = \hat{W}^T \sigma(\hat{V}^T x)$ with $\hat{V}, \hat{W}$ the estimated NN weights. Select the control input, $\tau = \hat{W}^T \sigma(\hat{V}^T x) + K_v r - v$ with K_v a symmetric positive definite gain and $v(t)$ a robustifying function. This NN control structure is shown in Fig. 1. The outer proportional-derivative (PD) tracking loop guarantees robust behavior. The inner loop containing the NN is known as a feedback linearization loop, and the NN effectively learns the unknown dynamics online to cancel the nonlinearities of the system. Let the estimated sigmoid Jacobian be $\hat{\sigma}' \equiv \frac{d\sigma(z)}{dz}\big|_{z=\hat{V}^T x}$. Then, the NN weight tuning laws are provided by

$$\dot{\hat{W}} = F\hat{\sigma}r^T - F\hat{\sigma}'\hat{V}^T x r^T - kF \|r\| \hat{W},$$

$$\dot{\hat{V}} = Gx(\hat{\sigma}'\hat{W}r)^T - kG \|r\| \hat{V},$$

with any constant symmetric matrices $F, G > 0$, and scalar tuning parameter $k > 0$.

NN Controller for Discrete-Time Systems

Most feedback controllers today are implemented on digital computers. This requires the specification of control algorithms in discrete time or digital form (Lewis et al. 1999). To design such controllers, one may consider the discrete-time dynamics $x_{k+1} = f(x_k) + g(x_k)u_k$ with unknown functions $f(\cdot), g(\cdot)$. The digital NN controller derived in this situation has the form of a feedback linearization controller shown in Fig. 1. One can derive tuning algorithms, for a discrete-time neural network controller with L layers, that guarantee system stability and robustness (Lewis et al. 1999). For the i-th layer, the weight updates are of the form

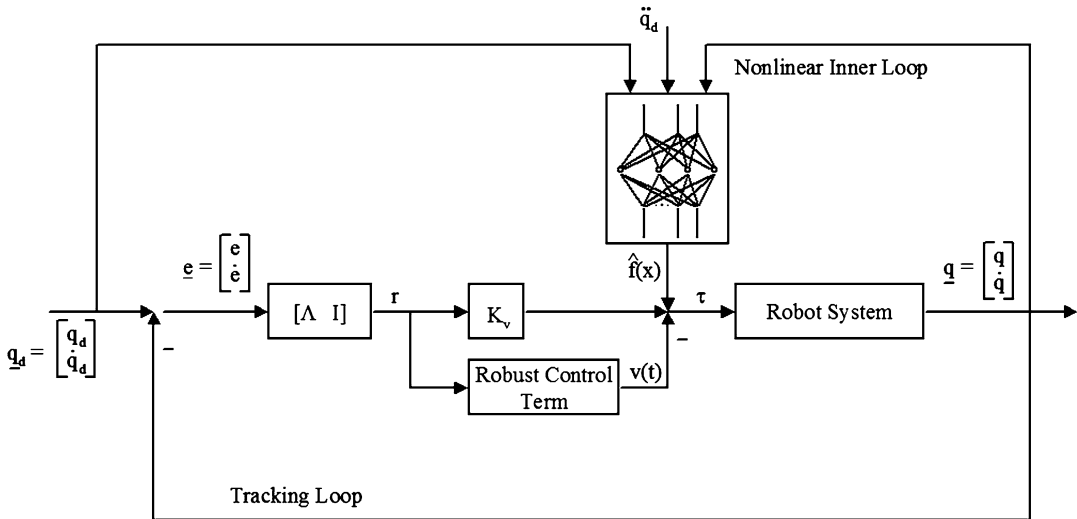
$$\hat{W}_i(k+1) = \hat{W}_i(k) - \alpha_i \hat{\phi}_i(k) \hat{y}_i^T(k) \\ - \Gamma \left\| I - \alpha_i \hat{\phi}_i(k) \hat{\phi}_i(k)^T \right\| \hat{W}_i(k)$$

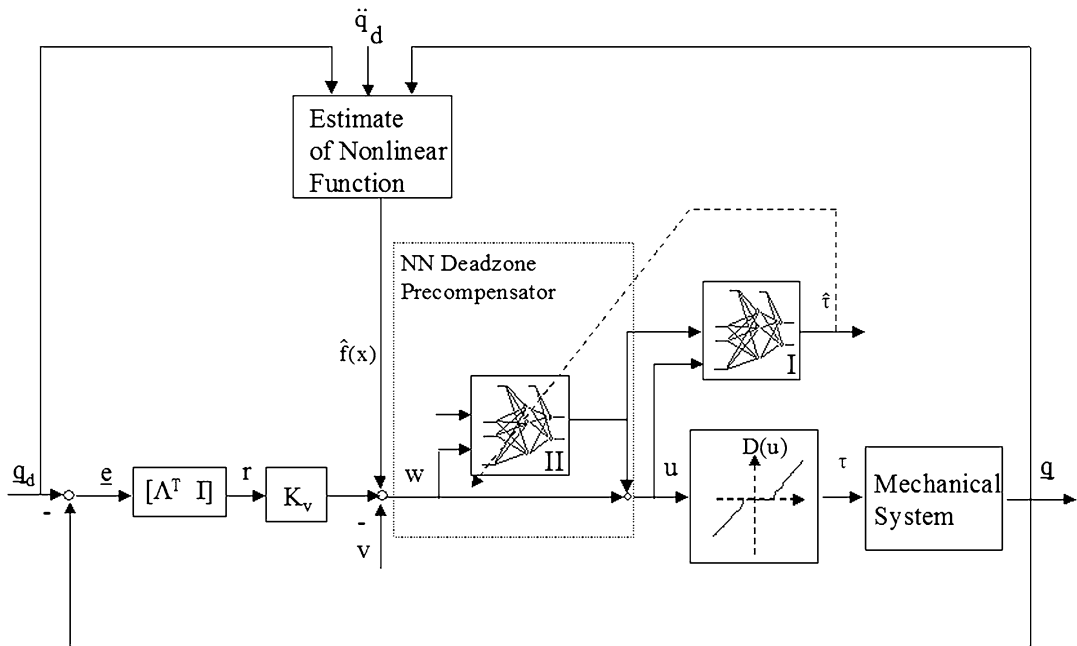
where $\hat{\phi}_i(k)$ are the output functions of layer i, $0 < \Gamma < 1$ is a design parameter, and

$$\hat{y}_i(k) = \begin{cases} \hat{W}_i^T \hat{\phi}_i(k) + K_v r(k) & \text{for } i = 1, \dots, L-1, \\ r(k+1) & \text{for } i = L \end{cases}$$

with $r(k)$ a filtered error.

Feedforward Neurocontroller

Industrial, aerospace, DoD, and MEMS assembly systems have actuators that generally contain deadzone, backlash, and hysteresis. Since these actuator nonlinearities appear in the feedforward loop, the NN compensator must also appear in the feedforward loop. This design is significantly more complex than for feedback NN controllers. Details are given in Lewis et al. (2002). Feedforward controllers can offset the effects of deadzone if properly designed. It can be shown that a NN deadzone compensator has the structure shown in Fig. 2.


Neural Control and Approximate Dynamic Programming, Fig. 1 Neural network robot controller


Neural Control and Approximate Dynamic Programming, Fig. 2 Feedforward NN for deadzone compensation

The NN compensator consists of two NNs. NN II is in the direct feedforward control loop, and NN I is not directly in the control loop but serves as an observer to estimate the (unmeasured) applied torque $\tau(t)$. The feedback stability and performance of the NN deadzone compensator have been rigorously proven using nonlinear stability proof techniques. The two NN were each selected as having one tunable layer, namely, the output weights. The activation functions were set as a basis by selecting fixed random values for the first-layer weights. To guarantee stability, the output weights of the inversion NN II (subscript i denotes weights and sigmoids of the inversion)

and the estimator NN I should be tuned respectively as

$$\dot{\hat{W}}_i = T\sigma_i(V_i w)r^T \hat{W}^T \sigma'(V^T u)V^T$$

$$- k_1 T \|r\| \hat{W}_i - k_2 T \|r\| \left\| \hat{W}_i \right\| \hat{W}_i,$$

$$\dot{\hat{W}} = -S\sigma'(V^T u)V^T \hat{W}_i \sigma_i(V_i^T w)r^T$$

$$- k_1 S \|r\| \hat{W},$$

with design matrices $T, S > 0$ and tuning gains k_1, k_2.

Approximate Dynamic Programming for Feedback Control

The current status of work in approximate dynamic programming (ADP) for feedback control is given in Lewis and Liu (2012). ADP is a form of reinforcement learning based on an actor/critic structure. Reinforcement learning (RL) is a class of methods used in machine learning to methodically modify the actions of an agent based on observed responses from its environment (Sutton and Barto 1998). The actor/critic structures are RL systems that have two learning structures: A critic network evaluates the performance of a current action policy, and based on that evaluation, an actor structure updates the action policy as shown in Fig. 3. Adaptive optimal controllers (Lewis et al. 2012b) have been proposed by adding optimality criteria to an adaptive controller or adding adaptive characteristics to an optimal controller.

Optimal Adaptive Control of Discrete-Time Nonlinear Systems

Consider a class of discrete-time systems described by the deterministic nonlinear dynamics in the affine state space difference equation form

$$x_{k+1} = f(x_k) + g(x_k)u_k, \qquad (2)$$

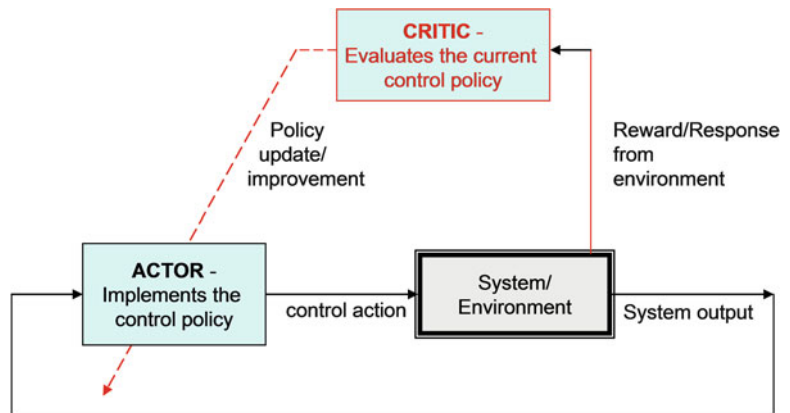
with state $x_k \in \mathbb{R}^n$ and control input $u_k \in \mathbb{R}^m$. A deterministic control policy is defined as a function from state space to control space $\mathbb{R}^n \to \mathbb{R}^m$. That is, for every state x_k, the policy defines a control action $u_k = h(x_k)$ as a feedback controller. Define a deterministic cost function that yields the value function:

$$V(x_k) = \sum_{i=k}^{\infty} \gamma^{i-k} r(x_i, u_i),$$

with $0 < \gamma \leq 1$ a discount factor, $Q(x_k)$, $R > 0$, and $u_k = h(x_k)$ a prescribed feedback control policy. The optimal value is given by Bellman's optimality equation:

$$V^*(x_k) = \min_{h(.)} \left(r(x_k, h(x_k)) + \gamma V^*(x_{k+1}) \right),$$

which is the discrete-time Hamilton-Jacobi-Bellman (HJB) equation. Two forms of RL can be based on policy iteration (PI) and value iteration (VI). For temporal difference learning, PI is

Neural Control and Approximate Dynamic Programming, Fig. 3 RL with an actor/critic structure


written as follows in terms of the deterministic Bellman equation.

Algorithm 1 PI for discrete-time systems
___
1: **procedure**
2:     Given admissible policies $h_0(x_k)$
3:     **while** $\left\| V^{h_i} - V^{h_i} \right\| \geq \epsilon_{ac}$ **do**
4:         Solve for the value $V_{(i)}(x)$ using

$$V_{i+1}(x_k) = r(x_k, h_i(x_k)) + \gamma V_{i+1}(x_{k+1})$$

5:         Update the control policy $h_{(i+1)}(x_k)$ using

$$h_{i+1}(x_k) = \arg\min_{h(\cdot)} \left(r(x_k, h(x_k)) + \gamma V_{i+1}(x_{k+1}) \right)$$

6:         $i := i + 1$
7:     **end while**
8: **end procedure**

---

where ϵ_{ac} is a small number that checks the algorithm convergence. Value iteration is similar, but the policy evaluation procedure is performed as $V_{i+1}(x_k) = r(x_k, h_i(x_k)) + \gamma V_i(x_{k+1})$. In value iteration, we can select any initial control policy, not necessarily admissible or stabilizing. In the control system shown in Fig. 3, the critic and the actor NNs are tuned online using the observed data $\left(x_k, x_{k+1}, r(x_k, h_i(x_k)) \right)$ along the system trajectory. The critic and actor are tuned sequentially in both the PI and the VI. That is, the weights of one neural network are held constant, while the weights of the other are tuned until convergence. This procedure is repeated until both neural networks have converged. Thus, the controller learns the optimal controller online. The convergence of value iteration using two neural networks for the discrete-time nonlinear system (2) is proven in Al-Tamimi et al. (2008). Design of an ADP controller that uses only output feedback is given in Lewis and Vamvoudakis (2011).

Optimal Adaptive Control of Continuous-Time Nonlinear Systems

RL is considerably more difficult for continuous-time systems than for discrete-time systems, and fewer results are available. This subsection will provide the formulation of optimal control problem followed by an offline PI algorithm provided

in Abu-Khalaf and Lewis (2005) that will give us the structure for the proposed online algorithms that follow. Consider the following nonlinear time-invariant affine in the input dynamical system given by

$$\dot{x}(t) = f(x(t)) + g(x(t))u(t); x(0) = x_0 \quad (3)$$

with $x(t) \in \mathbb{R}^n$, $f(x(t)) \in \mathbb{R}^n$, $g(x(t)) \in \mathbb{R}^{n \times m}$ and control input $u(t) \in \mathbb{R}^m$. We assume that $f(0) = 0$, $f(x) + g(x)u$ is Lipschitz continuous on a set $\Omega \subset \mathbb{R}^n$ that contains the origin and that the system is stabilizable on Ω, that is, there exists a continuous control function $u(t) \in U$ such that the system is asymptotically stable on Ω. Define the infinite horizon integral cost $\forall t \geq 0$

$$V(x_t) = \int_t^\infty r(x(\tau), u(\tau)) d\tau, \quad (4)$$

with $Q(x)$ positive definite and $R \in \mathbb{R}^{m \times m}$ a symmetric positive definite matrix. For any admissible control policy if the associated cost (4) is C^1, then an infinitesimal version is the Bellman equation, and the optimal cost function $V^*(x)$ is defined by

$$V^*(x_0) = \min_u \left(\int_0^\infty r(x, u) d\tau \right)$$

which satisfies the HJB equation. By employing the stationarity condition, the optimal control function for the given problem is

$$u^*(x) = -\frac{1}{2} R^{-1} g^T(x) \frac{\partial V^*(x)}{\partial x}. \quad (5)$$

Inserting the optimal control (5) into the Bellman equation, one obtains the formulation for HJB equation in terms of $\frac{\partial V^*(x)}{\partial x}$ and with boundary condition $V^*(0) = 0$

$$0 = r(x, u^*) + \frac{\partial V^*(x)}{\partial x}^T (f(x) + g(x)u^*), \quad (6)$$

which for the linear case becomes the well-known Riccati equation. In order to find the

optimal control solution for the problem, one needs to solve the HJB equations (6) for the value function and then substitute in (5) to obtain the optimal control. However, due to the nonlinear nature of the HJB equation, finding its solution is generally difficult or impossible. The following PI algorithm is an iterative algorithm for solving optimal control problems and will give us the structure for the online learning algorithm.

Algorithm 2 PI for continuous-time systems

1: **procedure**
2:     Given admissible policies $u^{(0)}$
3:     **while** $\left\| V^{u^{(i)}} - V^{u^{(i)}} \right\| \geq \epsilon_{ac}$ **do**
4:         Solve for the value $V^{(i)}(x)$ using Bellman's equation

$$Q(x) + \frac{\partial V^{u^{(i)}}}{\partial x}^T (f(x) + g(x)u^{(i)}) + u^{(i)^T} Ru^{(i)} = 0,$$

$$V^{u^{(i)}}(0) = 0$$

5:         Update the control policy $u^{(i+1)}$ using

$$u^{(i+1)} = -\left(\frac{1}{2} R^{-1} g^T(x) \frac{\partial V^{u^{(i)}}}{\partial x}^T \right)$$

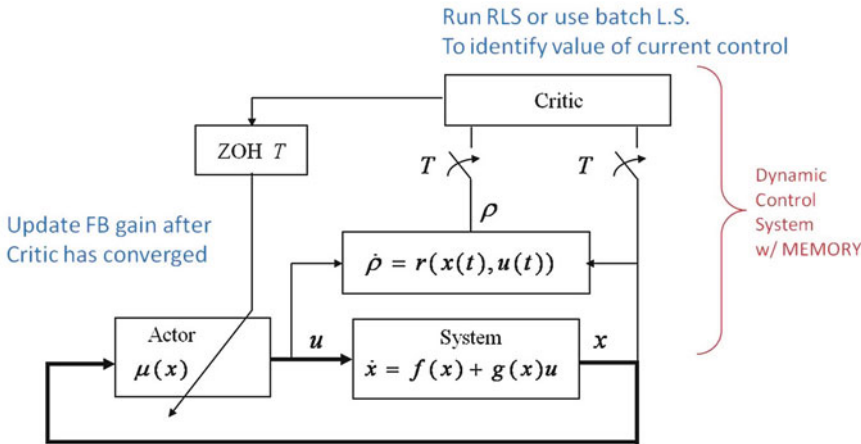
6:         $i := i + 1$
7:     **end while**
8: **end procedure**

A PI algorithm that solves online the HJB equation without full information of the plant dynamics is proposed in Vrabie et al. (2009) where the Bellman equation is proved to be equivalent to the *integral reinforcement learning form* with an optimal value given for some $T > 0$ as

$$V^*(x(t)) = \arg \min_u \int_t^{t+T} r(x(\tau), u(\tau)) d\tau + V^*(x(t+T)).$$

Therefore, the temporal difference error for continuous-time systems can be defined as

$$e(t : t + T) = \rho(t : t + T) + V(x(t+T)) - V(x(t)),$$

with $\rho(t : t + T) \equiv \int_t^{t+T} r(x(\tau), u(\tau)) d\tau$ without any information of the plant dynamics. The IRL controller just given tunes the critic neural network to determine the value while holding the control policy fixed. The IRL algorithm can be implemented online by RL techniques using value function approximation $\hat{V}(x) = \hat{W}_1^T \phi(x)$ in a critic approximator network. Using that approximation in the PI algorithm, one can use batch least squares or recursive least squares to update the value function, and then on convergence of the value parameters, the action is updated. The implementation of the IRL optimal adaptive control algorithm is shown in Fig. 4.


Neural Control and Approximate Dynamic Programming, Fig. 4 Hybrid optimal adaptive controller based on IRL

The work in Vamvoudakis and Lewis (2010) presents a way of finding the optimal control solution in a synchronous manner along with stability and convergence guarantees but with known dynamics. This procedure is more nearly in line with accepted practice in adaptive control.

A synchronous online learning algorithm that avoids the knowledge of drift dynamics is proposed in Vamvoudakis et al. (2013).

Learning in Games

Reinforcement learning techniques have been applied to design adaptive controllers that converge to the solution of two-player zero-sum games in Vamvoudakis and Lewis (2012) and Vrabie et al. (2012), of multiplayer nonzero-sum games in Vamvoudakis et al. (2012a), and of Stackelberg games in Vamvoudakis et al. (2012b). In these cases, the adaptive control structure has multiple loops, with action networks and critic networks for each player. The adaptive controller for zero-sum games finds the solution to the H-infinity control problem online in real time. This adaptive controller does not require any systems dynamics information.

Summary and Future Directions

This entry discusses some neuro-inspired adaptive control techniques. These controllers have multi-loop, multi-timescale structures and can learn the solutions to Hamilton-Jacobi design equations such as the Riccati equation online without knowing the full dynamical model of the system. A method known as Q learning allows the learning of optimal control solutions online, in the discrete-time case, for completely unknown systems. Q learning has not yet been fully investigated for continuous-time systems.

Nominal Model-Predictive Control

Lars Grüne
Mathematical Institute, University of Bayreuth, Bayreuth, Germany

Abstract

Model-predictive control is a controller design method which synthesizes a sampled data feedback controller from the iterative solution of open-loop optimal control problems. We describe the basic functionality of MPC controllers, their properties regarding feasibility, stability and performance, and the assumptions needed in order to rigorously ensure these properties in a nominal setting.

Keywords

Recursive feasibility; Sampled-data feedback; Stability

Introduction

Model-predictive control (MPC) is a method for the optimization-based control of linear and non-linear dynamical systems. While the literal meaning of "model-predictive control" applies to virtually every model-based controller design method, nowadays the term commonly refers to control methods in which pieces of open-loop optimal control functions or sequences are put together in order to synthesize a sampled data feedback law. As such, it is often used synonymously with "receding horizon control."

The concept of MPC was first presented in Propoǐ (1963) and was reinvented several times already in the 1960s. Due to the lack of sufficiently fast computer hardware, for a while these ideas did not have much of an impact. This changed during the 1970s when MPC was successfully used in chemical process control. At that time, MPC was mainly applied to linear systems with quadratic cost and linear constraints, since for this class of problems algorithms were sufficiently fast for real-time implementation – at least for the typically relatively slow dynamics of process control systems. The 1980s have then seen the development of theory and increasingly sophisticated concepts for linear MPC, while in the 1990s nonlinear MPC (often abbreviated as NMPC) attracted the attention of the MPC community. After the year 2000, several gaps in the analysis of nonlinear MPC without terminal constraints and costs were closed, and increasingly faster algorithms were developed. Together with the progress in hardware, this has considerably broadened the possible applications of both linear and nonlinear MPC.

In this entry, we explain the functionality of nominal MPC along with its most important properties and the assumptions needed to rigorously ensure these properties. We also give some hints on the underlying proofs. The term nominal MPC refers to the assumption that the mismatch between our model and the real plant is sufficiently small to be neglected in the following considerations. If this is not the case, methods from robust MPC must be used (▶ Robust Model-Predictive Control). We describe all concepts for nonlinear discrete time systems, noting that the basic results outlined in this entry are conceptually similar for linear and for continuous-time systems.

Model-Predictive Control

In this entry, we discuss MPC for discrete time control systems of the form

$$x_{\mathbf{u}}(j+1) = f(x_{\mathbf{u}}(j), u(j)), \ x_{\mathbf{u}}(0) = x_0 \quad (1)$$

with state $x_{\mathbf{u}}(j) \in X$, initial condition $x_0 \in \mathbb{X}$, and control input sequence $\mathbf{u} = (u(0), u(1), \ldots)$ with $u(k) \in U$, where the state space X and the control value space U are normed spaces. For control systems in continuous time, one may either apply the discrete time approach to a sampled data model of the system. Alternatively, continuous-time versions of the concepts and results from this entry are available in the literature; see, e.g., Findeisen and Allgöwer (2002) or Mayne et al. (2000).

The core of any MPC scheme is an optimal control problem of the form

$$\text{minimize } J_N(x_0, \mathbf{u}) \quad (2)$$

w.r.t. $\mathbf{u} = (u(0), \ldots, u(N-1))$ with

$$J_N(x_0, \mathbf{u}) : \sum_{j=0}^{N-1} \ell(x_{\mathbf{u}}(j), u(j)) + F(x_{\mathbf{u}}(N)) \quad (3)$$

subject to the constraints

$$u(j) \in \mathbb{U}, x_{\mathbf{u}}(j) \in \mathbb{X} \text{ for } j = 0, \ldots, N-1$$
$$x_{\mathbf{u}}(N) \in \mathbb{X}_0, \quad (4)$$

for control constraint set $\mathbb{U} \subseteq U$, state constraint set $\mathbb{X} \subseteq X$, and terminal constraint set $\mathbb{X}_0 \subseteq X$. The function $\ell : \mathbb{X} \times \mathbb{U} \to \mathbb{R}$ is called stage cost or running cost; the function $F : \mathbb{X} \to \mathbb{R}$ is referred to as terminal cost. We assume that for each initial value $x_0 \in \mathbb{X}$, the optimal control problem (2) has a solution and denote the corresponding minimizing control sequence by $\mathbf{u}^*$. Algorithms for computing $\mathbf{u}^*$ are discussed in ▶ Optimization Algorithms for Model Predictive Control and ▶ Explicit Model Predictive Control.

The key idea of MPC is to compute the values $\mu_N(x)$ of the MPC feedback law μ_N from the open-loop optimal control sequences $\mathbf{u}^*$. To formalize this idea, consider the closed-loop system

$$x_{\mu_N}(k+1) = f\left(x_{\mu_N}(k), \mu_N\left(x_{\mu_N}(k)\right)\right). \quad (5)$$

In order to evaluate μ_N along the closed-loop solution, given an initial value $x_{\mu_N}(0) \in \mathbb{X}$, we iteratively perform the following steps.

Basic MPC Loop
1. Set $k := 0$.
2. Solve (2)–(4) for $x_0 = x_{\mu_N}(k)$; denote the optimal control sequence by $\mathbf{u}^* = (u^*(0), \ldots, u^*(N-1))$.
3. Set $\mu_N(x_{\mu_N}(k)) : u^*(0)$, compute $x_{\mu_N}(k+1)$ according to (5), set $k := k+1$. and go to (1).

Due to its ability to handle constraints and possibly nonlinear dynamics, MPC has become one of the most popular modern control methods in the industry (▶ Model-Predictive Control in Practice). While in the literature various variants of this basic scheme are discussed, here we restrict ourselves to this most widely used basic MPC scheme.

When analyzing an MPC scheme, three properties are important:
- Recursive Feasibility, i.e., the property that the constraints (4) can be satisfied in Step (ii) in each sampling instant
- Stability, i.e., in particular convergence of the closed-loop solutions $x_{\mu_N}(k)$ to a desired equilibrium x_* as $k \to \infty$
- Performance, i.e., appropriate quantitative properties of $x_{\mu_N}(k)$

Here we discuss these three issues for two widely used MPC variants:
1. MPC with terminal constraints and costs
2. MPC with neither terminal constraints nor costs

In (a), F and $\mathbb{X}_0$ in (3) and (4) are specifically designed in order to guarantee proper performance of the closed loop. In (b), we set $F \equiv 0$ and $\mathbb{X}_0 = \mathbb{X}$. Thus, the choice of ℓ and N in (3) is the most important part of the design procedure.

N

Recursive Feasibility

Since the ability to handle constraints is one of the key features of MPC, it is important to ensure that the constraints $x_{\mu_N}(k) \in \mathbb{X}$ and $\mu_N(x_{\mu_N}(k)) \in \mathbb{U}$ are satisfied for all $k \geq 0$. However, beyond constraint satisfaction, the stronger property $x_{\mu_N}(k) \in \mathbb{X}_N$ is required, where $\mathbb{X}_N$ denotes the *feasible set* for horizon N,

$$\mathbb{X}_N := \{x \in \mathbb{X} | \text{ there exists } \mathbf{u} \text{ such that (4) holds}\}.$$

The property $x \in \mathbb{X}_N$ is called *feasibility* of x. Feasibility of $x = x_{\mu_N}(k)$ is a prerequisite for the MPC feedback μ_N being well defined, because the nonexistence of such an admissible control sequence $\mathbf{u}$ would imply that solving (2) under the constraints (4) in Step (ii) of the MPC iteration is impossible.

Since for $k \geq 0$ the state $x_{\mu_N}(k + 1) = f(x_{\mu_N}(k), u^*(0))$ is determined by the solution of the previous optimal control problem, the usual way to address this problem is via the notion of *recursive feasibility*. This property demands the existence of a set $A \subseteq \mathbb{X}$ such that:

- For each $x_0 \in A$, the problem (2)–(4) is feasible.
- For each $x_0 \in A$ and the optimal control $u^\star$ from (2) to (4), the relation $f(x_0, u^*(0)) \in A$ holds.

It is not too difficult to see that this property implies $x_{\mu_N}(k) \in A$ for all $k \geq 1$ if $x_{\mu_N}(0) \in A$.

For terminal-constrained problems, recursive feasibility is usually established by demanding that the terminal constraint set $\mathbb{X}_0$ is *viable* or *controlled forward invariant*. This means that for each $x \in \mathbb{X}_0$, there exists $u \in \mathbb{U}$ with $f(x, u) \in \mathbb{X}_0$. Under this assumption, it is quite straightforward to prove that the feasible set $A = \mathbb{X}_N$ is also recursively feasible (Grüne and Pannek 2011, Lemma 5.11). Note that viability of $\mathbb{X}_0$ is immediate if $\mathbb{X}_0 = \{x_*\}$ and $x_* \in \mathbb{X}$ is an equilibrium, i.e., a point for which there exists $u_* \in \mathbb{U}$ with $f(x_*, u_*) = x_*$. This setting is referred to as *equilibrium terminal constraint*.

For MPC without terminal constraints, the most straightforward way to ensure recursive feasibility is to assume that the state constraint set $\mathbb{X}$

is viable (Grüne and Pannek 2011, Theorem 3.5). However, checking viability and even more constructing a viable state constraint set is in general a very difficult task. Hence, other methods for establishing recursive feasibility are needed. One method is to assume that the sequence of feasible sets $\mathbb{X}_N$, $N \in \mathbb{N}$ becomes *stationary* for some N_0, i.e., that $\mathbb{X}_{N+1} = \mathbb{X}_N$ holds for all $N \geq N_0$. Under this assumption, recursive feasibility of $\mathbb{X}_{N_0}$ follows, see Kerrigan (2000, Theorem 5.3). However, like viability, stationarity is difficult to verify.

For this reason, a conceptually different approach to ensure recursive feasibility was presented in Grüne and Pannek (2011, Theorem 8.20); a similar approach for linear systems can be found in Primbs and Nevistić (2000). The approach is suitable for stabilizing MPC problems in which the stage cost ℓ penalizes the distance to a desired equilibrium x_* (cf. section "Stability"). Assuming the existence – but not the knowledge – of a viable neighborhood $\mathcal{N}$ of x_*, one can show that any initial point x_0 for which the corresponding open-loop optimal solution satisfies $x_{\mathbf{u}^*}(j) \in \mathcal{N}$ or some $j \leq N$ is contained in a recursively feasible set. The fact that ℓ penalizes the distance to x_* then implies $x_{\mathbf{u}^*}(j) \in \mathcal{N}$ for suitable initial values. Together, these properties yield the existence of recursively feasible sets A_N which become arbitrarily large as N increases.

Stability

Stability in the sense of this entry refers to the fact that a prespecified equilibrium $x_* \in \mathbb{X}$ – typically a desired operating point – is asymptotically stable for the MPC closed loop for all initial values in some set $\mathcal{S}$. This means that the solutions $x_{\mu_N}(k)$ starting in $\mathcal{S}$ converge to x_* as $k \to \infty$ and that solutions starting close to x_* remain close to x_* for all $k \geq 0$. Note that this setting can be extended to time-varying reference solutions; see ▶ Tracking Model Predictive Control.

In order to enforce this property, we assume that the stage cost ℓ penalizes the distance to the equilibrium x_* in the following sense: ℓ satisfies

$$\ell(x_*, u_*) = 0 \text{ and } \alpha_1(|x|) \leq \ell(x, u) \qquad (6)$$

for all $x \in \mathbb{X}$ and $u \in \mathbb{U}$. Here α_1 is a $\mathcal{K}_\infty$ function, i.e., a continuous function $\alpha_1 : [0, \infty) \to [0, \infty)$ which is strictly increasing, unbounded, and satisfies $\alpha_1(0) = 0$. With $|x|$, we denote the norm on X. In this entry, we exclusively discuss stage costs ℓ satisfying (6). More general settings using appropriate detectability conditions are discussed in Rawlings and Mayne (2009, Sect. 2.7) or Grimm et al. (2005) in the context of stabilizing MPC. Even more general ℓ are allowed in the context of economic MPC; see the ▶ Economic Model Predictive Control article.

In case of terminal constraints and terminal costs, a compatibility condition between ℓ and F is needed on $\mathbb{X}_0$ in order to ensure stability. More precisely, we demand that for each $x \in \mathbb{X}_0$ there exists a control value $u \in \mathbb{U}$ such that $f(x, u) \in \mathbb{X}_0$ and

$$F(f(x, u)) - F(x) \leq -\ell(x, u) \qquad (7)$$

holds. Observe that the condition $f(x, u) \in \mathbb{X}_0$ is again the viability condition which we already imposed for ensuring recursive feasibility. Note that (7) is trivially satisfied for $F \equiv 0$ in case of $\mathbb{X}_0 = \{x_*\}$ by choosing $u = u_*$.

Stability is now concluded by using the optimal value function

$$V_N(x_0) := \inf_{\mathbf{u} \text{ s.t. } (4)} J_N(x_0, \mathbf{u})$$

as a Lyapunov function. This will yield stability on $\mathcal{S} = \mathbb{X}_N$, as $\mathbb{X}_N$ is exactly the set on which V_N is defined. In order to prove that V_N is a Lyapunov function, we need to check that V_N is bounded from below and above by $\mathcal{K}_\infty$ functions α_1 and α_2 and that V_N is strictly decaying along the closed-loop solution.

The first amounts to checking

$$\alpha_1(|x|) \leq V_N(x) \leq \alpha_2(|x|) \qquad (8)$$

for all $x \in \mathbb{X}_N$. The lower bound follows immediately from (6) (with the same α_1), and the upper bound can be ensured by conditions

on the problem data (see, e.g., Rawlings and Mayne 2009, Sect. 4.5; Grüne and Pannek 2011, Sect. 5.3).

For ensuring that V_N is strictly decreasing along the closed-loop solutions, we need to prove

$$V_N(f(x, \mu_N(x))) \leq V_N(x) - \ell(x, \mu_N(x)). \quad (9)$$

In order to prove this inequality, one uses on the one hand the dynamic programming principle stating that

$$V_{N-1}(f(x, \mu_N(x))) = V_N(x) - \ell(x, \mu_N(x)). \tag{10}$$

On the other hand, one shows that (7) implies

$$V_{N-1}(x) \geq V_N(x) \qquad (11)$$

for all $x \in \mathbb{X}_N$. Inserting (11) with $f(x, \mu_N(x))$ in place of x into (10) then immediately yields (9). Details of this proof can be found, e.g., in Mayne et al. (2000), Rawlings and Mayne (2009), or Grüne and Pannek (2011). The survey Mayne et al. (2000) is probably the first paper which develops the conditions needed for this proof in a systematic way; a continuous-time version of these results can be found in Fontes (2001).

Summarizing, for MPC with terminal constraints and costs, under the conditions (6)–(8), we obtain asymptotic stability of x_* on $\mathcal{S} = \mathbb{X}_N$.

For MPC without terminal constraints and costs, i.e., with $\mathbb{X}_0 = \mathbb{X}$ and $F \equiv 0$, these conditions can never be satisfied, as (7) will immediately imply $\ell(x, u) = 0$ for all $x \in \mathbb{X}$, contradicting (6). Moreover, without terminal constraints and costs, one cannot expect (9) to be true. This is because without terminal constraints, the inequality $V_{N-1}(x) \leq V_N(x)$ holds, which together with the dynamic programming principle implies that if (9) holds, then it holds with equality. This, however, would imply that μ_N is the infinite horizon optimal feedback law, which – though not impossible – is very unlikely to hold.

Thus, we need to relax (9). In order to do so, instead of (9), we assume the relaxed inequality

$$V_N(f(x, \mu_N(x))) \leq V_N(x) - \alpha \ell(x, \mu_N(x))$$
$$\tag{12}$$

for some $\alpha > 0$ and all $x \in \mathbb{X}$, which is still enough to conclude asymptotic stability of x_* if (6) and (8) hold. The existence of such an α can be concluded from bounds on the optimal value function V_N . Assuming the existence of constants $\gamma_K \geq 0$ such that the inequality

$$V_K(x) \leq \gamma_K \min_{u \in \mathbb{U}} \ell(x, u) \tag{13}$$

holds for all $K = 1, \ldots, N$ and $x \in \mathbb{X}$, there are various ways to compute α from $\gamma_1, \ldots, \gamma_N$, see Grüne (2012, Sect. 3). The best possible estimate for α, whose derivation is explained in detail in Grüne and Pannek (2011, Chap. 6), yields

$$\alpha = 1 - \frac{(\gamma_N - 1) \prod\limits_{i=2}^{N} (\gamma_i - 1)}{\prod\limits_{i=2}^{N} \gamma_i - \prod\limits_{i=2}^{N} (\gamma_i - 1)}. \tag{14}$$

Though not immediately obvious, a closer look at this term reveals $\alpha \to 1$ as $N \to \infty$ if the γ_K are bounded. Hence, $\alpha > 0$ for sufficiently large N.

Summarizing the second part of this section, for MPC without terminal constraints and costs, under the conditions (6), (8), and (13), asymptotic stability follows on $\mathcal{S} = \mathbb{X}$ for all optimization horizons N for which $\alpha > 0$ holds in (14). Note that the condition (13) implicitly depends on the choice of ℓ. A judicious choice of ℓ can considerably reduce the size of the horizon N for which $\alpha > 0$ holds, see Grüne and Pannek (2011, Sect. 6.6) and thus the computational effort for solving (2)–(4).

Performance

Performance of MPC controllers can be measured in many different ways. As the MPC controller is derived from successive solutions of (2), a natural quantitative way to measure its performance is to evaluate the infinite horizon functional corresponding to (3) along the closed loop, i.e.,

$$J_\infty^{c\ell}(x_0, \mu_N) := \sum_{k=0}^{\infty} \ell \left(x_{\mu_N}(k), \mu_N \left(x_{\mu_N}(k) \right) \right)$$

with $x_{\mu_N}(0) = x_0$. This value can then be compared with the optimal infinite horizon value

$$V_\infty(x_0) := \inf_{\mathbf{u}: u(k) \in \mathbb{U}, x_{\mathbf{u}}(k) \in \mathbb{X}} J_\infty(x_0, \mathbf{u})$$

where

$$J_\infty(x_0, \mathbf{u}) := \sum_{k=0}^{\infty} \ell(x_{\mathbf{u}}(k), u(k)).$$

To this end, for MPC with terminal constraints and costs, by induction over (9) and using non-negativity of ℓ, it is fairly easy to conclude the inequality

$$J_\infty^{c\ell}(x_0, \mu_N) \leq V_N(x_0)$$

for all $x \in \mathbb{X}_N$. However, due to the conditions on the terminal cost in (7), V_N may be considerably larger than V_∞ and an estimate relating these two functions is in general not easy to derive (Grüne and Pannek 2011, Examples 5.18 and 5.19). However, it is possible to show that under the same assumptions guaranteeing stability, the convergence

$$V_N(x) \to V_\infty(x)$$

holds for $N \to \infty$ (Grüne and Pannek 2011, Theorem 5.21). Hence, we recover approximately optimal infinite horizon performance for sufficiently large horizon N.

For MPC without terminal constraints and costs, the inequality $V_N(x_0) \leq V_\infty(x_0)$ is immediate; however, (9) will typically not hold. As a remedy, we can use (12) in order to derive an estimate. Using induction over (12), we arrive at the estimate

$$J_\infty^{c\ell}(x_0, \mu_N) \leq V_N(x_0)/\alpha \leq V_\infty(x_0)/\alpha.$$

Since $\alpha \to 1$ as $N \to \infty$, also in this case we obtain approximately optimal infinite horizon performance for sufficiently large horizon N.

Summary and Future Directions

MPC is a controller design method which uses the iterative solution of open-loop optimal control problems in order to synthesize a sampled data feedback controller μ_N. The advantages of MPC are its ability to handle constraints, the rigorously provable stability properties of the closed loop, and its approximate optimality properties. Assumptions needed in order to rigorously ensure these properties together with the corresponding mathematical arguments have been outlined in this entry, both for MPC with terminal constraints and costs and without. Among the disadvantages of MPC are the computational effort and the fact that the resulting feedback is a full state feedback, thus necessitating the use of a state estimator to reconstruct the state from output data (▶ Moving Horizon Estimation).

Future directions include the application of MPC to more general problems than set point stabilization or tracking, the development of efficient algorithms for large-scale problems including those originating from discretized infinite-dimensional control problems, and the understanding of the opportunities and limitations of MPC in increasingly complex environments; see also ▶ Distributed Model Predictive Control.

Abstract

We consider the control of nonlinear systems in which parameters are uncertain and may vary. For such systems the control must adapt to the parameter change to deliver closed-loop performance, such as asymptotic stability or tracking. A concise description of available methods and basic adaptive stabilization results, which can be used as building blocks for complex adaptive control problems, are discussed.

Keywords

Adaptive stabilization; Linear parameterization; Lyapunov function; Nonlinear parameterization; Output feedback

Introduction

The adaptive control problem, namely, the problem of designing a feedback controller which contains an *adaptation mechanism* to counteract changes in the parameters of the system to be controlled, is of significant importance in applications. In almost all systems, physical parameters are subject to changes. These may be triggered, for example, by changes in temperature (the volume of a liquid/gas), aging (the friction coefficient of a mechanical system), or normal operation (the mass of the fuel of an aircraft changes during flight, the center of mass of a vehicle is affected by its load).

While adaptive control is naturally associated with the notion of estimation, i.e., the parameters of a system have to be identified to design a controller, it may be possible to design adaptive controllers which do not rely on a *complete* parameter estimation: it is sufficient to estimate the *effect* of the parameters on the control signal.

Adaptive control is different from robust control. In the simplest possible occurrence, the aim of robust control is to design a control law guaranteeing performance specifications for a given range of parameter values. Robust control thus requires some a priori information on the parameter. Adaptive control does not require any a priori information on the parameter, although any such information can be exploited in the controller design, but requires a parameterized model: a model which contains information on the way the parameters affect the dynamics of the system.

The adaptive control problem for general nonlinear systems can be formulated as follows. Consider a nonlinear system described by equations of the form

$$\dot{x} = F(x, u, \theta), \qquad\qquad y = H(x, \theta), \quad (1)$$

where $x(t) \in \mathbb{R}^n$ denotes the state of the system, $u(t) \in \mathbb{R}^m$ denotes the input of the system, $\theta \in \mathbb{R}^q$ denotes the constant unknown parameter, $y(t) \in \mathbb{R}^p$ denotes the measured output, and $F : \mathbb{R}^n \times \mathbb{R}^m \times \mathbb{R}^q \to \mathbb{R}^n$ and $H : \mathbb{R}^n \times \mathbb{R}^q \to \mathbb{R}^p$ are smooth mappings. While we focus on continuous-time systems, similar considerations apply to discrete-time systems. In what follows, for simplicity, we mostly assume that $y = x$: the whole state of the system is available for control design.

The adaptive control problem consists in finding, if possible, a dynamic control law described by equations of the form

$$\dot{\hat{\theta}} = w(x, \hat{\theta}, r), \qquad\qquad (2)$$

$$u = v(x, \hat{\theta}, r), \qquad\qquad (3)$$

with $r(t) \in \mathbb{R}^s$ an exogenous (reference) signal and $w : \mathbb{R}^n \times \mathbb{R}^q \times \mathbb{R}^s \to \mathbb{R}^q$ and $v : \mathbb{R}^n \times \mathbb{R}^q \times \mathbb{R}^s \to \mathbb{R}^m$ smooth mappings, such

that the closed-loop system, described by the equations

$$\dot{x} = F(x, v(x, \hat{\theta}, r), \theta), \qquad \dot{\hat{\theta}} = w(x, \hat{\theta}, r), \tag{4}$$

has specific properties. For example, one could require that all trajectories be bounded and the x-component of the state converge to a given value $x^{\star}$ (this is the so-called adaptive regulation requirement) or that the input-output behavior of the system from the input r to some user-defined output signal coincide with a given reference model (this is the so-called model reference adaptive control requirement).

A natural way to characterize design specifications for the adaptive control problem and to facilitate its solution is to assume the existence of a known parameter controller, described by the equation

$$u = v^{\star}(x, \theta, r), \tag{5}$$

such that the nonadaptive closed-loop system $\dot{x} = F(x, v^{\star}(x, \theta, r), \theta)$ satisfies given design specifications. In this perspective, the adaptive control problem boils down to the design of the *update law* (2) and of the *feedback law* (3) such that the behavior of the adaptive closed-loop system *matches* that of the nonadaptive closed-loop system $\dot{x} = F(x, v^{\star}(x, \theta, r), \theta)$.

The above description suggests a design method for the *feedback law*: one could replace θ with $\hat{\theta}$ in Eq. (5). This design is often known as certainty equivalence design and lends itself to the interpretation that $\hat{\theta}$ be an estimate for θ. Naturally, one could also modify the feedback law, replacing θ with $\hat{\theta}$ and adding x-dependant terms: this is often called a redesign. Redesign may be guided by various considerations, for example, it may be based on the use of a specific Lyapunov function (yielding the so-called Lyapunov redesign), or by structural properties of the system, or by robustness constraints.

The interpretation of $\hat{\theta}$ as an estimate for θ leads to two similar approaches for the design of the update law. The former, pursued in the so-called indirect adaptive control, relies on the design of a parameter estimator, for example,

using recursive least-square methods. This approach has its roots in identification theory and has been studied in-depth for linear systems. The latter relies on the observation that the design of an update law is equivalent to the design of a (reduced-order) observer for the extended system

$$\dot{x} = F(x, u, \theta), \qquad \dot{\theta} = 0,$$

with output $y = x$. This approach has its roots in the theory of nonlinear observer design.

The approaches described so far relies on a sort of separation principle: the update law and the feedback law are designed separately. While this approach may be adequate for linear systems, for nonlinear systems it is often necessary to design the update law and the feedback law in one step, i.e., the selection of the feedback law depends upon the selection of the update law and vice versa. To illustrate this design method, and provide some explicit adaptive control design tools, we focus on a special class of nonlinear systems: systems which are linearly parameterized in the unknown parameter.

Linearly Parameterized Systems

Consider the system (1) and assume the mapping F is affine in the parameter θ and in the control u, namely,

$$F(x, u, \theta) = f_0(x) + g(x)u + f_1(x)\theta, \tag{6}$$

with $f_0 : \mathbb{R}^n \to \mathbb{R}^n$, $g : \mathbb{R}^n \to \mathbb{R}^n \times \mathbb{R}^m$ and $f_1 : \mathbb{R}^n \to \mathbb{R}^n \times \mathbb{R}^q$ smooth mappings. For this class of systems, under additional assumptions, it is possible to provide systematic adaptive control design tools. We provide two formal results: additional results (depending on the specific assumptions imposed on the system) may be derived. In both cases the focus is on the adaptive stabilization problem: the goal of the adaptive controller is to render a given equilibrium stable, in the sense of Lyapunov, and to guarantee convergence of the x-component of the state (recall that the state of the adaptive closed-loop system is the vector $(x, \hat{\theta})$).

Theorem 1 *Consider the system (6) and a point x^*. Assume there exist a known parameter controller*

$$u = v_0(x) + v_1(x)\theta,$$

with $v_0 : \mathbb{R}^n \to \mathbb{R}^m$ and $v_1 : \mathbb{R}^n \to \mathbb{R}^m \times \mathbb{R}^q$ smooth mappings, and a positive definite and radially unbounded function $V : \mathbb{R}^n \to \mathbb{R}$, such that $V(x^\star) = 0$ and

$$\frac{\partial V}{\partial x} f^*(x, \theta) < 0$$

for all $x \neq x^\star$.

Then the update law

$$\dot{\hat{\theta}} = -\left(\frac{\partial V}{\partial x} g(x) v_1(x)\right)^\top$$

and the feedback law

$$u = v_0(x) + v_1(x)\hat{\theta}$$

are such that all trajectories of the closed-loop system are bounded and $\lim_{t \to \infty} x(t) = x^\star$.

Theorem 2 *Consider the system (6) and a point x^*. Assume there exists a known parameter controller $u = v(x, \theta)$ such that the closed-loop system*

$$\dot{x} = f^*(x, \theta),$$

where $f^*(x, \theta) = f_0(x) + f_1(x)\theta + g(x)v(x, \theta)$, has a globally asymptotically stable equilibrium at x^*. Assume, in addition, that there exists a mapping $\beta : \mathbb{R}^n \to \mathbb{R}^q$ such that all trajectories of the system

$$\dot{z} = -\left[\frac{\partial \beta}{\partial x} f_1(x)\right] z,$$
$$\dot{x} = f^*(x) + g(x)\left(v(x, \theta + z) - v(x, \theta)\right)$$
$$(7)$$

are bounded and satisfy

$$\lim_{t \to \infty} \left[g(x(t))\left(v(x(t), \theta + z(t)) - v(x(t), \theta)\right)\right] = 0.$$

Then the update law

$$\dot{\hat{\theta}} = -\frac{\partial \beta}{\partial x}\Big[f_0(x) + f_1(x)\big(\hat{\theta} + \beta(x)\big)$$
$$+ g(x)v(x, \hat{\theta} + \beta(x))\Big] \tag{8}$$

and the feedback law

$$u = v(x, \hat{\theta} + \beta(x))$$

are such that all trajectories of the closed-loop system are bounded and $\lim_{t \to \infty} x(t) = x^\star$.

The stability properties of the adaptive closed-loop system in Theorem 1 can be studied with the Lyapunov function $W(x, \hat{\theta}) = V(x) + \frac{1}{2}\|\hat{\theta} - \theta\|^2$, whereas a Lyapunov analysis for the adaptive closed-loop system of Theorem 2 can be carried out, under additional assumptions, via a Lyapunov function of the form $W(x, \hat{\theta}) = V(x) + \frac{1}{2}\|\hat{\theta} - \theta + \beta(x)\|^2$. This suggests that in Theorem 1 $\hat{\theta}$ plays the role of the estimate of θ, whereas in Theorem 2 such a role is played by $\hat{\theta} + \beta(x)$. Note that in none of the theorems, the parameter estimate is required to converge to the true value of the parameters, although in Theorem 2 the feedback law is required to converge, along trajectories, to the known parameter controller. This has a very important, possibly counterintuitive, consequence: the *asymptotic* nonadaptive controller $u = v(x, \hat{\theta}_\infty)$, where $\hat{\theta}_\infty = \lim_{t \to \infty} \hat{\theta}(t)$, provided the limit exists, is not in general a stabilizing controller for system (6).

Example 1 Consider the nonlinear system described by the equation $\dot{x} = u + \theta x^2$, with $x(t) \in \mathbb{R}$, $u(t) \in \mathbb{R}$, and $\theta \in \mathbb{R}$. A known parameter controller satisfying the assumptions of Theorem 1 (with and $V(x) = x^2/2$) and of Theorem 2 (with $\beta(x) = x$) is $u = -x - \theta x^2$. The resulting update laws and feedback laws are

$$\dot{\hat{\theta}}_1 = x^3, \qquad u_1 = -x - \hat{\theta}x^2,$$

and

$$\dot{\hat{\theta}}_2 = x, \qquad u_2 = -x - (\hat{\theta} + x)x^2,$$

respectively, the subscripts "1" and "2" are used to refer to the construction in Theorem 1 and 2, respectively.

The basic building blocks in Theorems 1 and 2 can be exploited repeatedly to design adaptive controllers for systems with a specific structure, for example, for systems described by the equations

$$
\begin{aligned}
\dot{x}_1 &= x_2 + \varphi_1(x_1)^\top \theta, \\
\dot{x}_2 &= x_3 + \varphi_2(x_1, x_2)^\top \theta, \\
&\vdots \\
\dot{x}_i &= x_{i+1} + \varphi_i(x_1, \ldots, x_i)^\top \theta, \\
&\vdots \\
\dot{x}_n &= u + \varphi_n(x_1, \ldots, x_n)^\top \theta,
\end{aligned}
\tag{9}
$$

with $x_i(t) \in \mathbb{R}$, for $i = 1, \ldots, n$, $u(t) \in \mathbb{R}$, $\varphi_i : \mathbb{R}^i \to \mathbb{R}^q$, for $i = 1, \ldots, n$, smooth mappings, and $\theta \in \mathbb{R}^q$. Note that the last of the equations (9) can be replaced by

$$
\dot{x}_n = \bar{\theta} u + \varphi_n(x_1, \ldots, x_n)^\top \theta,
$$

with $\bar{\theta} \in \mathbb{R}$, provided its sign is known (this condition may be removed using the so-called Nussbaum gain). The parameter $\bar{\theta}$ is often referred to as the high-frequency gain of the system: a terminology borrowed from linear systems theory.

Output Feedback Adaptive Control

A key feature of the parameterized systems described so far is that these are linearly parameterized in θ. The linear parameterization allows to develop systematic design tools, such as those given in Theorems 1 and 2. Such results, however, require full information on the state of the system. If only partial information on the state is available, one has to combine an estimator of the state with an update law. Such a combination requires either strong assumptions on the system or very specific structures. For example, it is feasible if the system is not only linearly parameterized in the parameter θ, but it is also linearly parameterized in the unmeasured states, namely, it is described by equations of the form

$$
\begin{aligned}
\dot{x}_1 &= x_2 + \psi_1(x_1) + \varphi_1(x_1)^\top \theta, \\
\dot{x}_2 &= x_3 + \psi_2(x_1) + \varphi_2(x_1)^\top \theta, \\
&\vdots \\
\dot{x}_i &= x_{i+1} + \psi_i(x_1) + \varphi_i(x_1)^\top \theta + b_i u, \\
&\vdots \\
\dot{x}_{n-1} &= x_n + \psi_{n-1}(x_1) + \varphi_{n-1}(x_1)^\top \theta + b_{n-1} u, \\
\dot{x}_n &= \psi_n(x_1) + \varphi_n(x_1)^\top \theta + b_n u, \\
y &= x_1
\end{aligned}
$$

with $x_i(t) \in \mathbb{R}$, for $i = 1, \ldots, n$, $u(t) \in \mathbb{R}$, $y(t) \in \mathbb{R}$, $\varphi_i : \mathbb{R} \to \mathbb{R}^q$, and $\psi_i : \mathbb{R} \to \mathbb{R}$, for $i = 1, \ldots, n$, smooth mappings, $\theta \in \mathbb{R}^q$, and $b = [b_i, \cdots, b_{n-1}, b_n]^\top$ unknown, but such that the sign of b_n is known and the polynomial $b_n s^{n-i} + b_{n-1} s^{n-i-1} + \cdots + b_i$ has all roots with negative real part (this implies that the system, with input u and output y, is minimum phase).

Nonlinear Parameterized Systems

Adaptive control of nonlinearly parameterized systems is an open area of research. The design of adaptive controllers relies often upon structural assumptions, for example, the existence of a monotonic parameterization, as in the system described by the equation

$$
\dot{x} = F(x, u) + \Phi(x, \theta),
$$

with $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, $\theta \in \mathbb{R}^q$, and $F : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$ and $\Phi : \mathbb{R}^n \times \mathbb{R}^q \to \mathbb{R}^n$ smooth mappings and such that, for all x, the mapping Φ satisfies the monotonicity condition

$$
(\theta_a - \theta_b)^\top (\Phi(x, \theta_a) - \Phi(x, \theta_b)) > 0,
$$

for all $\theta_a \neq \theta_b$. Alternatively, the design may exploit the so-called over-parameterization, for example, the equation of the system

$$
\dot{x} = u + \psi_1(x) \sin \theta + \psi_2(x) \cos \theta,
$$

with $x(t) \in \mathbb{R}$, $u(t) \in \mathbb{R}$, and $\theta \in \mathbb{R}$, may be rewritten in over-parameterized form as

$$\dot{x} = u + \psi_1(x)\theta_1 + \psi_2(x)\theta_2,$$

with $\theta_i \in \mathbb{R}$, for $i = 1, 2$. Note that the over-parameterized form *overlooks* the important information that $\theta_1^2 + \theta_2^2 = 1$.

Summary and Future Directions

The problem of adaptive stabilization for nonlinear systems has been discussed. Two conceptual building blocks for the design of stabilizing adaptive controllers have been discussed, and classes of systems for which these blocks allow to explicitly design adaptive controllers have been given. The role of parameter convergence, or lack thereof, has been briefly discussed together with connections between adaptive and observer designs. The difficulties associated with non-full state measurement and with nonlinear parameterization have been also briefly highlighted. Several problems have not been discussed, for example, model reference adaptive control, robust adaptive control, universal adaptive controllers, and the use of projections to incorporate prior knowledge on the parameter. Details on these can be found in the bibliography below.

Nonlinear Filters

Frederick E. Daum
Raytheon Company, Woburn, MA, USA

Abstract

Nonlinear filters estimate the state of dynamical systems given noisy measurements related to the state vector. In theory, such filters can provide optimal estimation accuracy for nonlinear measurements with nonlinear dynamics and non-Gaussian noise. However, in practice, the actual performance of nonlinear filters is limited by the curse of dimensionality. There are many different types of nonlinear filters, including the extended Kalman filter, the unscented Kalman filter, and particle filters.

Keywords

Bayesian; Computational complexity; Curse of dimensionality; Estimation; Extended Kalman filter; Non-Gaussian; Particle filter; Prediction; Smoothing; Stability; Unscented Kalman filter

Description of Nonlinear Filters

Nonlinear filters are algorithms that estimate the state vector (x) of a nonlinear dynamical system given measurements of nonlinear functions of the state vector corrupted by noise. Such filters also quantify the uncertainty in the resulting estimate of the state vector (e.g., using the error covariance matrix). Some nonlinear filters compute the entire probability density of the state vector conditioned on the set of measurements available, rather than computing a point estimate of the state vector (e.g., conditional mean or maximum likelihood). For some applications the conditional probability density of x is highly non-Gaussian (e.g., strongly multimodal). Even if the measurement noise and the process noise and the initial uncertainty in x are all Gaussian, the conditional density of x can be non-Gaussian, owing to the nonlinearities in the dynamics or measurements. The dynamical systems can evolve in continuous time or discrete time, and the measurements can be made in continuous time or at discrete times. The most popular nonlinear filter in practical applications is the extended Kalman filter (EKF), but there are many other families of nonlinear filters, including particle filters, unscented Kalman filters (UKFs), batch least squares, exact finite-dimensional filters, Gaussian sum filters, cubature Kalman filters, etc. Table 1 summarizes the most popular nonlinear filters. The theory for nonlinear filters is relatively simple (see Ho and Lee 1964), but the crucial practical issue is computational complexity, even today with fast modern inexpensive computers, e.g., graphical processing units (GPUs). See Ristic et al. (2004) for a book which is both accessible to engineers and thorough.

Bayesian Formulation of Filtering Problem

The Bayesian approach to nonlinear filters is by far the most popular formulation of the problem (see Ho and Lee 1964), and it has virtually eliminated all other competing theories, because it is simple, general, systematic, and useful. All ten nonlinear filters listed in Table 1 are Bayesian. The Bayesian approach uses a model of the dynamics of x as well as a model of the measurements. For example, discrete-time dynamics and measurement models are typically of the form

$$x(t_{k+1}) = f(x(t_k), t_k) + w(t_k)$$

$$z(t_k) = h(x(t_k), t_k) + v(t_k)$$

in which $x(t_k)$ is the d-dimensional state vector at time t_k, $z(t_k)$ is the m-dimensional measurement vector at time t_k, v is the measurement noise, and w is the so-called process noise. Both v and w are often modeled as Gaussian zero-mean random processes with statistically independent values at distinct discrete times, but these models could be highly non-Gaussian with statistically correlated random values. The initial probability density of x before any measurements are available is also used in the Bayesian formulations. Real physical systems are most commonly modeled as evolving in continuous time using Itô stochastic differential equations:

$$dx = f(x(t), t)dt + dw$$

However, most engineers would rather think of the above Itô equation as an ordinary differential equation driven by Gaussian white noise:

$$dx/dt = f(x(t), t) + dw/dt$$

Mathematicians prefer the Itô equation to avoid the embarrassment that the time derivative of w(t) does not exist. For details of stochastic calculus, see Jazwinski (1998). Such mathematical subtleties rarely cause any trouble in practical engineering applications. We emphasize, however, that it is important to correctly model continuous-

Nonlinear Filters, Table 1　Summary of nonlinear filters

Nonlinear filter	Conditional probability density	Computational complexity	Comments	References
1. Extended Kalman filter (EKF)	Gaussian	d^3	Gives good accuracy for many practical applications but can be highly suboptimal in difficult problems	Gelb et al. (1974)
2. Unscented Kalman filter(UKF)	Gaussian	d^3	Often the UKF beats the EKF, but sometimes the EKF is better than the UKF; see Noushin (2008) for details	Julier and Uhlmann (2003)
3. Batch least squares	Gaussian	d^3	Often beats the EKF accuracy but can fail for multimodal or other strongly non-Gaussian densities	Sorenson (1980)
4. Particle filter	Arbitrary	Varies from d^3 to exponential in d, depending on many features of the problem	Often beats the EKF accuracy but can fail due to the curse of dimensionality and particle degeneracy and ill-conditioning	Doucet (2011)
5. Cubature Kalman filter	Gaussian	d^3	Sometimes beats the EKF and UKF for difficult nonlinear non-Gaussian problems, but not always	Haykin (2010)
6. Gaussian sum	Arbitrary	Varies from d^3 to exponential in d, depending on many features of the problem	Beats the EKF for certain difficult nonlinear non-Gaussian problems	Sorenson (1988)
7. Exact finite-dimensional filters	Exponential family	d^3	Beats the EKF for certain difficult nonlinear non-Gaussian problems	Daum (2005)
8. Implicit particle filters	Arbitrary	Suffers from the curse of dimensionality (i.e., computation time grows exponentially in d)	Only low-dimensional numerical examples have been published so far	Chorin (2009)
9. Particle flow filter	Arbitrary	Faster than standard particle filters by many orders of magnitude for high-dimensional problems (but unfortunately there is no explicit formula for computation time)	Beats the EKF by orders of magnitude for certain difficult nonlinear non-Gaussian problems	Daum (2013)
10. Numerical solution of Fokker-Planck equation	Arbitrary	Suffers from the curse of dimensionality (i.e., computation time grows exponentially in d)	Beats the EKF by orders of magnitude for certain difficult nonlinear non-Gaussian problems	Ristic (2004)

time random processes for the evolution of the state vector (x) in many practical applications. Similarly, one can model measurements in continuous time using Itô calculus:

$$dz = h(x(t), t)dt + dv$$

Most engineers consider continuous-time measurement models as impractical and unnecessarily complicated mathematically, because digital computers always require discrete-time measurements and there are no practical analog computers that can be used for nonlinear filtering, owing to the overwhelming superiority of digital computers in terms of accuracy, stability, dynamic range, and flexibility. Nevertheless, there are many papers published by researchers using continuous-time measurement models. But the vast majority of practical papers on nonlinear filters use discrete time measurement models for obvious reasons. This contrasts sharply with the practical importance of correctly modeling continuous-time random processes for the evolution of the state vector (x).

Nonlinear Filter Algorithms

There is no universally best nonlinear filter for all applications, and there is much debate about which is the best nonlinear filter for any given application. Even if we knew the best nonlinear filter for a given computer, the answer could be very different for a different computer; in particular, some filters can exploit massively parallel processing architectures, whereas others cannot. Research and development of nonlinear filters should continue rapidly for the foreseeable future. More generally, there is no universal theory of computational complexity for practical algorithms of this type; perhaps the closest approximation to such a theory is "information-based complexity" (IBC); e.g., see Traub and Werschulz (1998) and Dick et al. (2013). The estimation accuracy of x and the computational complexity of the nonlinear filter are intimately connected, as shown below for particle filters.

There is no useful way to quantify the computational complexity of nonlinear filters without also quantifying estimation accuracy of x. This contrasts with standard computational complexity theory (e.g., P vs. NP) because we are interested in approximations rather than exact solutions. This is the basic idea of IBC. In practice, engineers compare the estimation accuracy and computational complexity of different nonlinear filters using Monte Carlo simulations for specific applications and specific computers.

The most active area of current research in nonlinear filters is focused on particle filters, which have the promise of optimal accuracy for essentially any nonlinear filter problem, at the cost of very high computational complexity for high-dimensional problems. In the early days (1994–2004), researchers often asserted that particle filters "beat the curse of dimensionality," but it is well known today that this assertion is wrong (e.g., see Daum 2005). Unfortunately, there is no useful theory of computational complexity for particle filters, but rather the currently available theory gives asymptotic bounds on accuracy with generic "constants." Such bounds on the variance of estimation error are generally of the form c/N in which N is the number of particles and c is the generic so-called constant. But we know that the so-called constant actually varies by many orders of magnitude depending on the specifics of the problem, including the following: (1) dimension of the state vector being estimated, (2) uncertainty in the initial state vector, (3) measurement accuracy, (4) stability of the dynamical system that describes the time evolution of the state vector, (5) geometry of the conditional probability densities (e.g., unimodal, log-concave, multimodal, etc.), (6) Lipschitz constants of the log probability densities, (7) curvature of the nonlinear dynamics and measurements, (8) ill-conditioning of the Fisher information matrix for the estimation problem, etc. Moreover, there are no tight bounds on the so-called constant c for practical nonlinear filter problems, but rather the best bounds for simple MCMC problems are known to be 30 orders of magnitude too large; see Dick et al. (2013).

Discrete-Time Measurement Models

Research papers on nonlinear filters are often mathematically abstract, but advanced math is not required for practical engineering applications (e.g., see Ho and Lee 1964). In particular, one can avoid the advanced stochastic mathematics used for continuous-time measurements by using discrete-time measurements, which is the practical case of interest anyway, owing to the use of digital computers to implement such algorithms. The notion that continuous-time measurements results in simpler, better, or more elegant results for nonlinear filters is misleading; for example, we have the elegant innovation theory for continuous-time measurements (Kailath 1970), but this theory is not applicable for discrete-time measurements, likewise with the elegant formula for propagating the conditional mean for continuous-time measurements (the so-called Fujisaki-Kallianpur-Kunita formula). More generally, the simple discrete-time version of Bayes' rule suffices for practical real-world engineering applications; there is rarely a need to employ the more complex continuous-time version. The discrete time formula for Bayes' rule is simply

$$p(x(t_k), t_k|Z_k) = p(x(t_k), t_k|Z_{k-1})p(z_k|x(t_k))/p(z_k|Z_{k-1})$$

in which

$p(x(t_k), t_k|Z_k)$ = probability density of x at time t_k conditioned on Z_k; this is also called the "posteriori probability density"

$x(t)$ = state vector of the dynamical system at time t

Z_k = set of all measurements up to and including time t_k

z_k = measurement vector at time t_k

$p(z_k|x(t_k))$ = probability density of z_k conditioned on $x(t_k)$; this is also called the "likelihood"

$p(A|B)$ = probability density of A conditioned on B

This is all one needs to know about Bayes' rule for practical engineering applications of nonlinear filtering; see Ho and Lee (1964). Bayes' rule is a simple formula that multiplies two probability densities and normalizes it by dividing by $p(z_k|Z_{k-1})$. In most applications, there is no need to normalize the density, and hence, Bayes' rule for the unnormalized conditional density is even simpler:

$$p(x(t_k), t_k|Z_k) = p(x(t_k), t_k|Z_{k-1})p(z_k|x(t_k))$$

We see that Bayes' rule for the unnormalized conditional density is simply a multiplication of two densities (i.e., the likelihood and the prior).

Summary and Future Directions

In practical applications, the most popular nonlinear filter is the extended Kalman filter (EKF), followed by the unscented Kalman filter (UKF). These two filters give good accuracy and robust performance for many practical applications. The computational complexity of both the EKF and UKF grows as the cube of the dimension of the state vector, and hence, they are very practical to run in real time on laptops or PCs for many real- world applications. But there are also many difficult nonlinear or non-Gaussian problems for which the EKF and UKF give suboptimal accuracy, and in some cases, they give surprisingly bad accuracy. The accuracy of optimal nonlinear filters is limited by the curse of dimensionality. We know how to write the equations for the optimal nonlinear filter, but the solution generally takes an exponentially increasing time to compute as the dimension of the state vector grows. There are many different kinds of nonlinear filters, and this is still an active field of research, as shown in Crisan and Rozovskii (2011). Future research is likely to exploit advances in computational complexity theory for approximation of functions in the style of information-based complexity (IBC) rather than P vs. NP theory. This is because we want good fast approximations rather than exact algorithms. A lucid introduction to IBC is Traub and Werschulz (1998), and recent work is surveyed in Dick et al. (2013). Another fruitful direction of research is to exploit the recent advances in transport theory,

as explained in Daum (2013); the best introduction to transport theory is the book by Villani (2003), which is very accessible yet thorough. Research in exact finite-dimensional filters is difficult but could yield substantial improvements in accuracy and computational complexity; for example, see Benes (1981), Marcus (1984), and Daum (2005). Progress in nonlinear filter research could be inspired by many diverse fields, including fluid dynamics, quantum chemistry, quantum field theory, gauge theory, string theory, Lie superalgebras, Lie supergroups, and neuroscience. An important open research topic is the stability of nonlinear filters, which is obviously a fundamental limitation to good theoretical upper bounds on estimation error. We still do not have a practical theory of stability for nonlinear filters. Perhaps the closest approximation to such a theory is the lucid paper by van Handel (2010), which makes an interesting attempt at understanding the stability of nonlinear filters. In particular, van Handel's paper aims to generalize Kalman's theory of stability for the Kalman filter by connecting stability with the essence of controllability and observability. A good survey of what is known about stability theory for nonlinear filters is given in various articles in Crisan and Rozovskii (2011).

Nonlinear Sampled-Data Systems

Dragan Nesic[1] and Romain Postoyan[2,3]
[1]Department of Electrical and Electronic Engineering, The University of Melbourne, Melbourne, VIC, Australia
[2]Université de Lorraine, CRAN, France
[3]CNRS, CRAN, France

Abstract

Sampled-data systems are control systems in which the feedback law is digitally implemented via a computer. They are prevalent nowadays due to the numerous advantages they offer compared to analog control. Nonlinear sampled-data systems arise in this context when either the plant model or the controller is nonlinear. While their linear counterpart is now a mature area, nonlinear sampled-data systems are much harder to deal with and, hence, much less understood. Their inherent complexity leads to a variety of methods for their modeling, analysis, and design. A summary of these methods is presented in this entry.

Keywords

Discrete time; Nonlinear; Sampled data; Sampler; Zero-order hold

Introduction

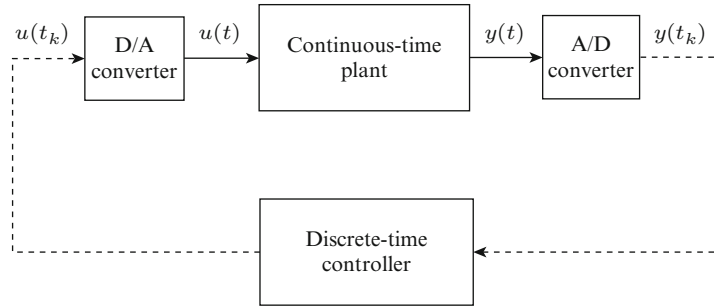
Definition: A control system in which a continuous-time plant is controlled by a digital computer is referred to as a *sampled-data control system* or simply a *sampled-data system* (Chen and Francis 1994); see Fig. 1. *Nonlinear sampled-data systems* arise when either the model of the plant or the controller is nonlinear; otherwise the system is referred to as a linear sampled-data system.

Motivation: Sampled-data control is preferable to continuous-time (analog) control for a range of reasons including reduced cost, reduced wiring, more robust hardware, easier and more flexible programming, and so on. Nowadays, a large majority of controllers are implemented on digital computers, and, hence, sampled-data systems are prevalent in practice. On the other hand, nonlinear plant models are necessary in numerous applications when a wide range of operating conditions need to be considered or when truly nonlinear phenomena, such as friction or state/input constraints, are not negligible. Hence, there are many situations where nonlinear plant models are essential, such as vertical takeoff and landing of an aircraft, robots, automotive engines, and biochemical reactors, to name a few. It has to be noted that the nonlinearity may also come from the controller even when we consider linear plants as it is the case in adaptive control or model predictive control with constraints, for example.

Structure of sampled-data systems: Figure 1 presents a typical structure of a sampled-data system which consists of a continuous-time plant, an analog-to-digital (A/D) converter (i.e., a sampler), a digital-to-analog (D/A) converter (i.e., a hold device), and a discrete-time controller.

The A/D converter takes measurements $y(t_k)$ of a continuous-time output signal $y(t)$, such as temperature or pressure, at sampling time instants $t_k, k = 0, 1, \ldots$ and sends them to the control algorithm. The measurements are obtained with finite precision (i.e., they are quantized); this effect is not considered in this entry. The sampling instants t_k are often equidistant, that is, $t_k = kT$, $k = 0, 1, \ldots$, where the distance T between any two consecutive sampling instants is referred to as the *sampling period*. The sampling period is an important degree of freedom in the design of sampled-data systems and it needs to be carefully selected.

The control algorithm is discrete in nature. It takes the sequence of measurements $y(t_k)$ and processes them to produce a sequence of control values $u(t_k)$. The D/A converter converts the sequence of control values $u(t_k)$ into a continuous-time signal $u(t)$ that drives the actuators which control the plant. Typically, a zero-order hold is used, i.e., $u(t) = u(t_k), \forall t \in [t_k, t_{k+1})$. However, it is possible to use other types of holds.

Nonlinear Sampled-Data Systems, Fig. 1
Sampled-data (control) system


Note that the system in Fig. 1 can be generalized in many ways. An important generalization is *multi-rate sampling* where the output of the system is sampled at one sampling rate while the control inputs are updated at a different sampling rate. Another generalization are *networked control systems* which are discussed in the last section.

Modeling

The combination of continuous-time and discrete-time components renders the analysis and the design of sampled-data systems challenging. Still, linear systems allow for computationally efficient analysis and design techniques that benefit from the z and δ transforms, as well as convex optimization (Chen and Francis 1994). Nonlinear sampled-data systems, one the other hand, are much harder to deal with since the aforementioned methods do not apply in this case. This inherent difficulty has led to a variety of models for different analysis and design methods:

1. Continuous-time models
2. Discrete-time models
3. Sampled-data models

We discuss bellow each of these models, their features, and the analysis or design methods that exploit them.

Continuous-time models basically ignore the sampling process and assume that all signals are continuous time. They are the coarsest approximation of the sampled-data system and they are useful only for very small sampling periods. Nevertheless, they are invaluable and are used as the first step in the controller/observer design in the so-called *emulation* design approach.

Discrete-time models only capture the behavior of the sampled-data system at sampling instants. Indeed, they ignore the inter-sample behavior of the system and this is their main drawback. There are two ways in which nonlinear discrete-time models arise: (i) from the identification of the plant model using the sampled measurements and (ii) from the discretization of a known continuous-time plant model. For instance, black box identification methods often lead to nonlinear discrete-time models in input-output form, such as NARMA (nonlinear autoregressive moving average) models (Chen et al. 1989; Juditsky et al. 1995). Depending on the approximating functions used, the nonlinearities can be polynomial, neural network type, fuzzy type, and so on. On the other hand, the discretization of the continuous-time plant model requires an exact analytic solution of a set of nonlinear differential equations. When such an analytic solution exists, we can obtain the exact discrete-time models of the system; this is typically assumed for linear plants. Nonlinear sampled-data systems are different from their linear counterparts in that it is typically impossible to obtain the exact discrete-time model and only approximate discrete-time models are available for analysis and design (Nešić et al. 1999; Nešić and Teel 2004).

Sampled-data models capture the true behavior of the sampled-data system including its

inter-sample behavior. There are several ways in which this can be achieved. One way is to model the piecewise constant signals that arise from zero-order hold devices as signals with a time-varying delay; this gives rise to time-delay nonlinear models (Teel et al. 1998). Another recently proposed approach is to model nonlinear sampled-data systems as hybrid dynamical systems (Goebel et al. 2012). An extensive analysis and design toolbox has been developed for hybrid dynamical systems and these results can be used for nonlinear sampled-data systems. Another class of models, based on the so-called lifting, has been applied for linear systems where the system is represented as a discrete-time system with infinite dimensional input and output spaces. While this approach has been very successful in the linear context (Chen and Francis 1994), it appears that it is not as useful for nonlinear systems due to difficulties arising from harder analysis and prohibitive computational requirements.

The Main Issues and Analysis

Controllability/observability: Issues arising due to sampling in linear systems transfer to the nonlinear context although they are less understood in this case. For instance, it is well known that sampling may "destroy" the controllability and/or observability properties of the system (Chen and Francis 1994). In other words, if the continuous-time plant model is controllable/observable, then the corresponding exact discrete-time model of the plant may not verify these properties for some sampling periods. A simple test is available for linear systems to avoid this phenomenon, but we are not aware of similar results in the nonlinear context.

Finite escape times: A major difference between continuous-time linear and nonlinear systems is that the former have well defined solutions for constant control inputs and arbitrarily long sampling periods. This is not the case, in general, for nonlinear systems as they may exhibit finite escape times. In other words, for a constant input it may happen for some initial

conditions of a nonlinear system that solutions blow up within a time that is shorter than the sampling period. As a consequence, for such an initial condition and input, the exact discrete-time system cannot be defined. This is a fundamental obstacle to achieving global stability results for nonlinear systems if the sampling period is fixed and independent of the size of the initial state. Nevertheless, it is possible to ensure semi-global stability properties for very general nonlinear systems which means that any compact domain of convergence can be achieved if the sampling period is sufficiently reduced (Nešić and Teel 2004).

Model structure is changed: An important issue for nonlinear sampled-data systems is that the sampling modifies the structure of the model. When the continuous-time plant model has a certain structure, such as triangular or affine in the input, the corresponding exact discrete-time model will not inherit it; see Monaco and Normand-Cyrot (2007) and Yuz and Goodwin (2005). This significantly complicates the design of sampled-data systems via the discrete-time approach since many nonlinear design techniques, like backstepping or forwarding, are heavily reliant on the structure of the model.

Zero dynamics: Probably the most significant aspect of the changed structure are the so-called sampling zeros. In linear systems, it is well known that if a continuous-time linear system of relative degree $r \geq 2$ is sampled, then generically for fast sampling the discrete-time models of the plant will have relative degree $r = 1$. In other words, sampling introduces extra zeros in the model which are often unstable and thus render the system non-minimum phase. It is well known that the controller design is much harder for non-minimum phase systems, and, moreover, there are certain fundamental performance limitations in this case. Recently, results that extend the notion of sampling zeros to the nonlinear sampled-data systems have been reported; see the references in Monaco and Normand-Cyrot (2007).

Passivity: Some plant properties like passivity are much more restrictive in discrete time than in continuous time. Indeed, it is necessary for a

continuous-time plant to have relative degree 1 or 0 to be passive, whereas only relative degree 0 discrete-time plants may possess this property. In other words, an exact discrete-time model of a passive continuous-time plant of relative degree 1 will not be passive; that is, sampling typically destroys passivity.

Controller Design

Linearization: The simplest way to design sampled-data nonlinear systems is to linearize the plant at a given operating point. In this case, the nonlinear plant dynamics are approximated by a linear model around a chosen equilibrium, and then any of the linear sampled-data techniques can be applied to the linearized model. The obtained solution is then implemented on the true nonlinear plant. The drawback of this technique is that the solution would typically perform well only in the vicinity of the selected equilibrium point.

Nonlinear methods: An alternative is to perform designs that rely on a nonlinear plant model. These approaches can be divided into feedback linearization, emulation design method, (approximate and exact) discrete-time design method, and sampled-data design method.

Feedback linearization: Some classical problems, like feedback linearization, are harder for sampled-data systems than continuous-time ones. It was shown that a class of discrete-time nonlinear systems for which feedback linearization is possible is smaller than the corresponding class of continuous-time systems (Grizzle 1987). This has led to approximate feedback linearization techniques which consider achieving feedback linearization approximately with an error that can be reduced by reducing the length of the sampling period (Arapostathis et al. 1989).

Continuous-time design method (Emulation design): Emulation is a design technique consisting of two steps. In the first step, a continuous-time controller or observer is designed for the continuous-time plant while ignoring sampling to achieve appropriate stability, performance, and/or robustness guarantees. In the second step,

the designed controller/observer is discretized for implementation and the sampling period is reduced sufficiently for the method to work. This method is approximate since the continuous-time plant model approximates well the sampled-data systems only for sufficiently small sampling periods. The discretization can be done using various implicit or explicit Runge-Kutta methods, such as the forward or backward Euler method (Monaco and Normand-Cyrot 2007; Yuz and Goodwin 2005). The emulation method is probably the best understood of all design methods. It was shown that a range of stability properties that can be cast in terms of dissipation inequalities are preserved in an appropriate sense under the emulation approach (Laila et al. 2002). Moreover, nonconservative estimates of the upper bound for the required sampling period in emulation have been reported recently (Nešić et al. 2009).

Exact discrete-time design method: Exact discrete-time design method assumes that an exact discrete-time model of the plant is available to the designer; see Kötta (1995) and the references cited therein. This approach is reasonable when black box identification techniques are used for modeling. Moreover, in some rare cases it is possible to obtain the exact discrete-time model of the plant by integrating the continuous-time model with fixed inputs (assuming the zero-order hold is used). This is the case when the plant dynamics are linear while the control law is nonlinear (e.g., adaptive control) or the plant is linear with state/input constraints, which is a setup often used in the model predictive control. The literature on exact discrete-time design method is vast and many of the nonlinear continuous-time design techniques, like backstepping, forwarding, and passivity-based designs, are extended to discrete-time nonlinear systems; see Kötta (1995) and Grizzle (1987). A drawback of these methods is that they assume a special structure of the discrete-time nonlinear model, such as upper or lower triangular structure, which is typically much more restrictive in discrete-time than in continuous-time due to the loss of structure due to sampling that was discussed earlier.

Approximate discrete-time design method: Due to the nonlinearity, it is impossible in most cases to obtain an exact discrete-time plant model by integrating its continuous-time model equations; instead, a range of approximate discrete-time plant models, such as Runge-Kutta, can be used for controller/observer design. It was recently shown that this design method may lead to disastrous consequences where the controller stabilizes the approximate discrete-time plant model for all (arbitrarily small) sampling periods while the same controller destabilizes the exact discrete-time plant model for all sampling periods; see Nešić and Teel (2004) and Nešić et al. (1999). This is true even for linear systems and some commonly used discretization techniques and controller designs. These considerations have led to the development of a framework for controller design based on approximate discrete-time models (Nešić et al. 1999; Nešić and Teel 2004). This framework provides checkable conditions on the continuous-time plant model, the approximate discrete-time model and the controller that guarantee that the controllers designed in this manner would stabilize the exact discrete-time model and, hence, the nonlinear sampled-data system for sufficiently small sampling periods. The design is based on families of approximate discrete-time models parameterized with the sampling period, and the design objectives are more demanding than in the continuous-time nonlinear systems. Ideas from numerical analysis are adapted to this context. This framework was used to design controllers and observers for classes of nonlinear sampled-data systems where typically Euler approximate discretization is employed to generate the approximate discrete-time model.

Sampled-data design method: Both emulation and discrete-time design methods have their drawbacks. Indeed, the former method ignores the sampling at the design stage, whereas the latter method ignores and may produce unacceptable inter-sampling behavior. Thus, methods that use a sampled-data model of the plant for design are much more attractive. There are two possible ways in which this can be achieved for nonlinear sampled-data systems.

The first approach consists of representing nonlinear sampled-data systems as systems with time-varying delays (Teel et al. 1998). However, controller design tools for such systems need to be further developed.

The second approach involves representing the nonlinear sampled-data system as a hybrid dynamical system. Recent advances on modeling and analysis of hybrid dynamical systems (Goebel et al. 2012) offer great opportunities in this context, but the full potential of this approach is still to be exploited. Nonlinear sampled-data systems are just a small subclass of hybrid dynamical systems, and developing specific analysis and design tools tailored to this class of systems seems promising.

It should be emphasized that there are many related techniques, such as discrete-time adaptive control and model predictive control, that deal with classes of nonlinear sampled-data systems but are not a part of the mainstream nonlinear sampled-data literature.

Summary and Future Directions

Summary: Sampled-data control systems are nowadays prevalent and there are many situations where nonlinear models need to be used to deal with wider ranges of operating conditions, more restrictive constraints, and enhanced performance specifications. Despite their increasing importance, the design of nonlinear sampled-data systems remains largely unexplored, and it is much less developed than its continuous-time counterpart. A variety of models, analysis, and design techniques make nonlinear sampled-data literature very diverse and a comprehensive textbook reference or a unifying approach is still missing. Many open questions remain for nonlinear sampled-data systems, such as results on multi-rate sampling, design techniques based on sampled-data models, and other generalizations which are discussed below.

Future Directions: In the 1990s, a new generation of digitally controlled systems has evolved from the more classical sampled-data systems

which are generally referred to as networked control systems (NCS); see Heemels et al. (2010) and the references cited therein. These systems exploit digital wired or wireless communication networks within the control loops. Such a setup is introduced to reduce the cost, weight, and volume of the engineered systems, but its special structure imposes new challenges due to the communication constraints, data packet dropouts, quantization of data, varying sampling periods, time delays, etc. At the same time, these systems provide new flexibilities due to the distributed computation within the control system that can be used to improve the performance and mitigate some of the undesirable network effects on the overall system performance. Moreover, embedded microprocessors allow for event-triggered and self-triggered sampling (Anta and Tabuada 2010) that are still largely unexplored especially for nonlinear systems. Design of NCS was identified as one of the biggest challenges to the control research community in the twenty-first century, and more than a decade of intense research on this topic still has not provided a comprehensive and unifying approach for their analysis and design. Novel results on modeling and Lyapunov stability theory for (nonlinear) hybrid dynamical systems appear to offer the right analysis design tools but they are still to be converted into efficient and easy-to-use design tools in the control engineers' toolbox.

Nonlinear System Identification Using Particle Filters

Thomas B. Schön
Department of Information Technology, Uppsala University, Uppsala, Sweden

Abstract

Particle filters are computational methods opening up for systematic inference in nonlinear/non-Gaussian state-space models. The particle filters constitute the most popular sequential Monte Carlo (SMC) methods. This is a relatively recent development, and the aim here is to provide a brief exposition of these SMC methods and how they are key enabling algorithms in solving nonlinear system identification problems. The particle filters are important for both frequentist (maximum likelihood) and Bayesian nonlinear system identification.

Keywords

Bayesian; Backward simulation; Maximum likelihood; Markov chain Monte Carlo (MCMC); Particle filter; Particle MCMC; Particle smoother; Sequential Monte Carlo

Introduction

The state-space model (SSM) offers a general tool for modeling and analyzing dynamical phenomena. The SSM consists of two stochastic processes: the states $\{\mathbf{x}_t\}_{t \geq 1}$ and the measurements $\{\mathbf{y}_t\}_{t \geq 1}$, which are related according to

$$\mathbf{x}_{t+1} \mid (\mathbf{x}_t = x_t) \sim f_\theta(x_{t+1} \mid x_t, u_t), \quad (1a)$$

$$\mathbf{y}_t \mid (\mathbf{x}_t = x_t) \sim h_\theta(y_t \mid x_t, u_t), \quad (1b)$$

and the initial state $\mathbf{x}_1 \sim \mu_\theta(x_1)$. We use bold face for random variables and $\sim$ means "distributed according to." The notation $\mathbf{x}_{t+1} \mid (\mathbf{x}_t = x_t)$ stands for the conditional probability of $\mathbf{x}_{t+1}$ given $\mathbf{x}_t = x_t$. The state process $\{\mathbf{x}_t\}_{t \geq 1}$ is a

Markov process, implying that we only need to condition on the most recent state $\mathbf{x_t}$, since that contains all information about the past. Furthermore, θ denotes the parameters, $f_\theta(\cdot)$ and $h_\theta(\cdot)$ that are probability density functions, encoding the dynamic and the measurement models, respectively. In the interest of a compact notation, we will suppress the input u_t throughout the text.

The SSM introduced in (1) is general in that it allows for nonlinear and non-Gaussian relationships. Furthermore, it includes both black-box and gray-box models on state-space form. Nonlinear black-box and gray-box models are covered by ▶ Nonlinear System Identification: An Overview of Common Approaches. The offline nonlinear system identification problem can (slightly simplified) be expressed as recovering information about the parameters θ based on the information in the T measured inputs $u_{1:T} \triangleq \{u_1, \ldots, u_T\}$ and outputs $y_{1:T}$. For a thorough exposition of the system identification problem, we refer to ▶ System Identification: An Overview. Nonlinear system identification has a long history, and a common assumption of the past has been that of linearity and Gaussianity. This assumption is very restrictive, and we have now witnessed well over half a century of research devoted to finding useful approximate algorithms allowing this assumption to be weakened. This development has significantly intensified during the past two decades of research on sequential Monte Carlo (SMC) methods (including particle filters and particle smoothers). However, the use of SMC for nonlinear system identification is more recent than that. The aim here is to introduce the key ideas enabling the use of SMC methods in solving nonlinear system identification problems, and as we will see, it is not a matter of straightforward application. The development of SMC-based identification follows two clear trends that are indeed more general: (1) The problems we are working with are analytically intractable, and hence, the mindset has to shift from searching for closed-form solutions to the use of *computational methods*, and (2) the new algorithms have basic building blocks that are themselves algorithms. Both these trends call for new developments.

Before the SMC methods are introduced in section "Sequential Monte Carlo", their need is clearly explained by formulating both the Bayesian and the maximum likelihood identification problems in sections "Bayesian Problem Formulation" and "Maximum Likelihood Problem Formulation", respectively. Solutions to these problems are then provided in sections "Bayesian Solutions" and "Maximum Likelihood Solutions", respectively. Finally, we give some intuition for online (recursive) solutions in section "Online Solutions", and in section "Summary and Future Directions", we conclude with a summary and directions for future research.

Bayesian Problem Formulation

In formulating the Bayesian problem, the parameters θ are modeled as unknown stochastic variables, i.e., the model (1) needs to be augmented with a prior density for the parameters $\boldsymbol{\theta} \sim p(\theta)$. The aim in Bayesian system identification is to compute the posterior density of $\boldsymbol{\theta}$ given the measurements $p(\theta \mid y_{1:T})$. More generally, we typically compute the joint posterior of the parameters $\boldsymbol{\theta}$ and the states $\mathbf{x}_{1:T}$,

$$p(\theta, x_{1:T} \mid y_{1:T}) = p(x_{1:T} \mid \theta, y_{1:T}) p(\theta \mid y_{1:T}). \tag{2}$$

By explicitly including the state variables $\mathbf{x}_{1:T}$ in the problem formulation according to (2), they take on the role of auxiliary variables. The reason for including the state variables $\mathbf{x}_{1:T}$ as auxiliary variables is that the alternative of excluding them would require us to analytically marginalize the states $\mathbf{x}_{1:T}$. This is not possible for the model (1) under study. However, once we have an approximation of $p(\theta, x_{1:T} \mid y_{1:T})$ available, the density $p(\theta \mid y_{1:T})$ is easily obtained by straightforward marginalization.

Maximum Likelihood Problem Formulation

In formulating the maximum likelihood (ML) problem, the parameters θ are modeled as unknown deterministic variables. The ML formulation offers a systematic way of computing point

estimates of the unknown parameters θ in a model, by making use of the information available in the obtained measurements $y_{1:T}$. The ML estimate is obtained by finding the θ that maximizes the so-called log-likelihood function, which is defined as

$$\ell_T(\theta) \triangleq \log p_\theta(y_{1:T}) = \sum_{t=1}^{T} \log p_\theta(y_t \mid y_{1:t-1}). \tag{3}$$

Note that we use θ as a subindex to denote that the corresponding probability density function is parameterized by θ, analogously to what was done in (1). The one step ahead predictor $p_\theta(y_t \mid y_{1:t-1})$ is computed by marginalizing $p(y_t, x_t \mid y_{1:t-1}) = h_\theta(y_t \mid x_t) p_\theta(x_t \mid y_{1:t-1})$ w.r.t. x_t, i.e., integrating out x_t from $p(y_t, x_t \mid y_{1:t-1})$. To summarize, the ML estimate $\hat{\theta}^{\text{ML}}$ is obtained by solving the following optimization problem:

$$\hat{\theta}^{\text{ML}} \triangleq \arg\max_{\theta} \ \sum_{t=1}^{T} \log \int h_\theta(y_t \mid x_t)$$
$$p_\theta(x_t \mid y_{1:t-1}) \mathrm{d}x_t. \tag{4}$$

This problem formulation clearly reveals the important fact that the nonlinear state inference problem (here computing $p_\theta(x_t \mid y_{1:t-1})$) is inherent in any maximum likelihood formulation for identification of SSMs. For linear Gaussian models, the Kalman filter offers closed-form solutions for the state inference problem, but for nonlinear models, there are no closed-form solutions available.

Sequential Monte Carlo

Solving the nonlinear system identification problem implicitly requires us to solve various nonlinear state inference problems. We will, for example, need to approximate the smoothing density $p(x_{1:T} \mid y_{1:T})$ and the filtering density $p(x_t \mid y_{1:t})$. The SMC samplers offer approximate solutions to these and other nonlinear state inference problems, where

the accuracy is only limited by the available computational resources. This section only deals with the state inference problem, allowing us to drop the θ in the notation for brevity.

Most SMC samplers hinge upon importance sampling, motivating section "Importance Sampling". In section "Particle Filter", we make use of importance sampling in computing an approximation of the filtering density $p(x_t \mid y_{1:t})$, and in section "Particle Smoother", a particle smoothing strategy is introduced to approximately compute $p(x_{1:T} \mid y_{1:T})$.

Importance Sampling

Let $\mathbf{z}$ be a random variable distributed according to some complicated density $\pi(z)$ and let $\varphi(\cdot)$ be some function of interest. Importance sampling offers a systematic way of evaluating integrals of the form

$$\mathrm{E}\left[\varphi(\mathbf{z})\right] = \int \varphi(z)\pi(z)\mathrm{d}z, \quad (5)$$

without requiring samples directly generated from $\pi(z)$. The density $\pi(z)$ is referred to as the *target* density, i.e., the density we are trying to sample from. The importance sampler relies on a *proposal* density $q(z)$, from which it is simple to generate samples, let $\mathbf{z}^i \sim q(z)$, $i = 1, \ldots, N$. Since each sample $\mathbf{z}^i$ is drawn from the proposal density rather than from the target density $\pi(z)$, we must somehow account for this discrepancy. The so-called importance weights $\tilde{\mathbf{w}}^i = \pi(\mathbf{z}^i)/q(\mathbf{z}^i)$ encode the difference. By normalizing the weights $\mathbf{w}^i = \tilde{\mathbf{w}}^i / \sum_{j=1}^{N} \tilde{\mathbf{w}}^j$, we obtain a set of weighted samples $\{\mathbf{z}^i, \mathbf{w}^i\}_{i=1}^{N}$ that can be used to approximately evaluate the integral (5) resulting in $\mathrm{E}\left[\varphi(\mathbf{z})\right] \approx \sum_{i=1}^{N} \mathbf{w}^i \varphi(\mathbf{z}^i)$. Schön and Lindsten (2014) provide an introduction to importance sampling within a dynamical systems setting, whereas Robert and Casella (2004) provide a general treatment.

Particle Filter

The solution to the nonlinear filtering problem is provided by the following two recursive equations:

$$p(x_t \mid y_{1:t}) = \frac{h(y_t \mid x_t)p(x_t \mid y_{1:t-1})}{p(y_t \mid y_{1:t-1})}, \quad (6a)$$

$$p(x_t \mid y_{1:t-1}) = \int f(x_t \mid x_{t-1})$$

$$p(x_{t-1} \mid y_{1:t-1})\mathrm{d}x_{t-1}. \quad (6b)$$

In the general case (1) there are no analytical solutions available for the above equations. The particle filter maintains an empirical approximation of the solution, which at time $t-1$ amounts to

$$\hat{p}^N(x_{t-1} \mid y_{1:t-1}) = \sum_{i=1}^{N} \mathbf{w}_{t-1}^i \delta_{\mathbf{x}_{t-1}^i}(x_{t-1}), \quad (7)$$

where $\delta_{\mathbf{x}_{t-1}^i}(x_{t-1})$ denotes the Dirac delta mass located at $\mathbf{x}_{t-1}^i$. Furthermore, $\mathbf{w}_{t-1}^i$ and $\mathbf{x}_{t-1}^i$ are referred to as the weights and the particles, respectively. We will now derive the particle filter by designing an importance sampler allowing us to approximately solve (6). The derivation is performed in an inductive fashion, starting by assuming that $p(x_{t-1} \mid y_{1:t-1})$ is approximated by (7). Inserting (7) into (6b) results in $\hat{p}^N(x_t \mid y_{1:t-1}) = \sum_{i=1}^{N} \mathbf{w}_{t-1}^i f(x_t \mid \mathbf{x}_{t-1}^i)$, which is used in (6a) to compute an *approximation* of the filtering density $p(x_t \mid y_{1:t})$ up to proportionality. Hence, this allows us to target $p(x_t \mid y_{1:t})$ using an importance sampler, where the form of $\hat{p}^N(x_t \mid y_{1:t-1})$ suggests that new samples can be proposed according to

$$\mathbf{x}_t^i \sim q(x_t \mid y_{1:t}) = \sum_{i=1}^{N} \mathbf{w}_{t-1}^i f(x_t \mid \mathbf{x}_{t-1}^i). \quad (8)$$

It is worth noting that we can obtain a more general algorithm by replacing $f(x_t \mid \mathbf{x}_{t-1}^i)$ in the above mixture with a density $q(x_t \mid \mathbf{x}_{t-1}^i, y_t)$. However, in the interest of a simple, but still highly useful algorithm, we keep (8). The proposal density (8) is a weighted mixture consisting of N components, which means that we can generate a sample $\tilde{\mathbf{x}}_t^i$ from it via a two-step procedure: first we select which component to sample from, and secondly we generate a sample from that component. More precisely, the first

Algorithm 1 Bootstrap particle filter (for $i = 1, \ldots, N$)
1. **Initialization ($t = 1$):**
   (a) Sample $\mathbf{x}_1^i \sim \mu(x_1)$.
   (b) Compute the importance weights $\widetilde{\mathbf{w}}_1^i = h(y_1 \mid \mathbf{x}_1^i)$ and normalize $\mathbf{w}_1^i = \widetilde{\mathbf{w}}_1^i / \sum_{j=1}^N \widetilde{\mathbf{w}}_1^j$.
2. **For $t = 2$ to T do:**
   (a) Resample $\{\mathbf{x}_{t-1}^i, \mathbf{w}_{t-1}^i\}$ resulting in equally weighted particles $\{\widetilde{\mathbf{x}}_{t-1}^i, 1/N\}$.
   (b) Sample $\mathbf{x}_t^i \sim f(x_t \mid \widetilde{\mathbf{x}}_{t-1}^i)$.
   (c) Compute the importance weights $\widetilde{\mathbf{w}}_t^i = h(y_t \mid \mathbf{x}_t^i)$ and normalize $\mathbf{w}_t^i = \widetilde{\mathbf{w}}_t^i / \sum_{j=1}^N \widetilde{\mathbf{w}}_t^j$.

part amounts to selecting one of the N particles $\{\mathbf{x}_{t-1}^i\}_{i=1}^N$ according to

$$\mathbb{P}\left(\widetilde{\mathbf{x}}_{t-1} = \mathbf{x}_{t-1}^i \mid \{\mathbf{x}_{t-1}^j, \mathbf{w}_{t-1}^j\}_{j=1}^N\right) = \mathbf{w}_{t-1}^i,$$

where the selected particle is denoted as $\widetilde{\mathbf{x}}_{t-1}$. By repeating this N times, we obtain a set of equally weighted particles $\{\widetilde{\mathbf{x}}_{t-1}^i\}_{i=1}^N$, constituting an empirical approximation of $p(x_{t-1} \mid y_{1:t-1})$, analogously to (7). We can then draw $\mathbf{x}_t^i \sim f(x_t \mid \widetilde{\mathbf{x}}_{t-1}^i)$ to generate a realization from the proposal (8). This procedure that turns a weighted set of samples into an unweighted one is commonly referred to as *resampling*.

Finally, using the approximation $\hat{p}^N(x_t \mid y_{1:t-1})$ in (6a) and the proposal density according to (8) allows us to compute the weights as $\widetilde{\mathbf{w}}_t^i = h(y_t \mid \mathbf{x}_t^i)$. Once all the N weights are computed and normalized, we obtain a collection of weighted particles $\{\mathbf{x}_t^i, \mathbf{w}_t^i\}_{i=1}^N$ targeting the filtering density at time t. We have now (in a slightly nonstandard fashion) derived the so-called *bootstrap particle filter*, which was the first particle filter introduced by Gordon et al. (1993) two decades ago. Since the introduction of Algorithm 1, the surrounding theory and practice have undergone significant developments; see, e.g., Doucet and Johansen (2011) for an up-to-date survey. The weights $\{\mathbf{w}_{1:T}^i\}_{i=1}^N$ and the particles $\{\mathbf{x}_{1:T}^i\}_{i=1}^N$ are random variables, and in executing the algorithm, we generate one realization from these. This is a useful insight both when it comes to understanding, but also when it comes to the analysis of the

particle filters. There is by now a fairly good understanding of the convergence properties of the particle filter; see, e.g., Doucet and Johansen (2011) for basic results and further pointers into the literature.

Particle Smoother

A particle smoother is an SMC method targeting the joint smoothing density $p(x_{1:T} \mid y_{1:T})$ (or one of its marginals). There are several different strategies for deriving particle smoothers. Rather than mentioning them all, we introduce one powerful and increasingly popular strategy based on *backward simulation*, giving rise to the family of *forward filtering/backward simulation* (FFBSi) samplers.

In an FFBSi sampler the joint smoothing density $p(x_{1:T} \mid y_{1:T})$ is targeted by complementing a forward particle filter with a second recursion evolving in the time-reversed direction. The following factorization of the joint smoothing density

$$p(x_{1:T} \mid y_{1:T}) = \left(\prod_{t=1}^{T-1} p(x_t \mid x_{t+1}, y_{1:t})\right) p(x_T \mid y_{1:T}),$$

immediately suggests a highly useful time-reversed recursion. Start by generating a sample $\widetilde{x}_T \sim p(x_T \mid y_{1:T})$. We then continue generating samples backward in time by sampling from the so-called backward kernel $p(x_t \mid x_{t+1}, y_{1:t})$ according to $\widetilde{x}_t \sim p(x_t \mid \widetilde{x}_{t+1}, y_{1:t})$, for $t = T - 1, \ldots, 1$. The resulting sample $\widetilde{\mathbf{x}}_{1:T} \triangleq (\widetilde{x}_1, \ldots, \widetilde{x}_T)$ is then by construction a sample from the joint smoothing density. Hence, in performing M backward simulations, we obtain the following approximation of the joint smoothing density:

$$\hat{p}^M(x_{1:T} \mid y_{1:T}) = \sum_{i=1}^M \frac{1}{M} \delta_{\widetilde{\mathbf{x}}_{1:T}^i}(x_{1:T}). \qquad (9)$$

For details on how to design algorithms implementing the backward simulation strategy,

derivations, properties, and references, we refer to the recent survey on backward simulation methods by Lindsten and Schön (2013).

Bayesian Solutions

Strategies

The posterior density (2) is analytically intractable, but we can make use of Markov chain Monte Carlo (MCMC) samplers to address the inference problem. An MCMC sampler allows us to approximately generate samples from an arbitrary target density $\pi(z)$. This is done by simulating a Markov chain (i.e., a Markov process) $\{z[r]\}_{r \geq 1}$, which is constructed in such a way that the stationary distribution of the chain is given by $\pi(z)$. The sample paths $\{z[r]\}_{r=1}^{R}$ of the chain can then be used to draw inference about the target distribution. Two *constructive* ways of finding a suitable Markov chain to simulate are provided by the Metropolis Hastings (MH) and the Gibbs samplers, where the latter can be interpreted as a special case of the former. See, e.g., Robert and Casella (2004) for details on MCMC. A Gibbs sampler targeting $p(\theta, x_{1:T} \mid y_{1:T})$ is given by

(i) Draw $\theta' \sim p(\theta \mid x_{1:T}, y_{1:T})$.

(ii) Draw $x'_{1:T} \sim p(x_{1:T} \mid \theta', y_{1:T})$.

The second step is hard, since it requires us to generate a sample from the joint smoothing density. Simply replacing step (ii) with a backward simulator does not result in a valid method (Andrieu et al. 2010).

One interesting solution is provided by the family of particle MCMC (PMCMC) sampler, first introduced by Andrieu et al. (2010). PMCMC provides a systematic way of combining SMC and MCMC, where SMC is used to construct the proposal density for the MCMC sampler. The so-called *particle Gibbs* (PG) sampler resolves the problems briefly mentioned above by a nontrivial modification of the SMC algorithm. Introducing the PG sampler lies outside the scope of this work; we refer the reader to the ground-breaking work by Andrieu et al. (2010). During the past 3 years, the PG samplers have developed quite a lot, and improved versions are surveyed and explained by Lindsten and Schön (2013).

A Nontrivial Example

To place PMCMC in the context of nonlinear system identification, we will now solve a nontrivial identification problem. The PG sampler is used to compute the posterior density for a general Wiener model (linear Gaussian system followed by a static nonlinearity) (Giri and Bai 2010):

$$\mathbf{x}_{t+1} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \end{pmatrix} \begin{pmatrix} \mathbf{x}_t \\ \mathbf{u}_t \end{pmatrix} + \mathbf{v}_t, \qquad \mathbf{v}_t \sim \mathcal{N}(0, \mathbf{Q}), \tag{10a}$$

$$\mathbf{z}_t = \mathbf{C}\mathbf{x}_t, \tag{10b}$$

$$\mathbf{y}_t = \mathbf{g}(\mathbf{z}_t) + \mathbf{e}_t, \qquad \mathbf{e}_t \sim \mathcal{N}(0, \mathbf{r}). \tag{10c}$$

Based on observed inputs $u_{1:T}$ and outputs $y_{1:T}$, we wish to identify the model (10). We place a matrix normal inverse Wishart (MNIW) prior on $\{(\mathbf{A}, \mathbf{B}), \mathbf{Q}\}$, an inverse gamma prior on $\mathbf{r}$, and a Gaussian process (Rasmussen and Williams 2006) prior on the function $\mathbf{g}$, resulting in a semiparametric model. We can without loss of generality fix the matrix C according to $C = (1, 0, \dots, 0)$. For a complete model specification, we refer to Lindsten et al. (2013).

The posterior distribution $p(\theta, x_{1:T} \mid y_{1:T})$ is computed using a newly developed PG sampler referred to as particle Gibbs with ancestor sampling (PGAS); see Lindsten and Schön (2013). In the present experiment we make use of $T = 1,000$ observations. The dimension of the state–space is 6, the linear dynamics contains complex poles resulting in oscillations as seen in Fig. 1, and the nonlinearity is non-monotonic; see Fig. 2. A subspace method is used to find an initial guess for the linear system, and the static nonlinearity is initialized using a linear function (i.e., a straight line).

Nonlinear System Identification Using Particle Filters, Fig. 1
Bode diagram of the sixth-order linear system. The *black curve* is the true system. The *red curve* is the estimated posterior mean of the Bode diagram, and the *shaded area* is the 99 % Bayesian credibility interval
Nonlinear System Identification Using Particle Filters, Fig. 2 The *black curve* is the true static nonlinearity (non-monotonic). The *red curve* is the estimated posterior mean of the static nonlinearity, and the *shaded area* is the 99 % Bayesian credibility interval

It is worth pausing for a moment to reflect upon the posterior distribution $p(\theta, x_{1:T} \mid y_{1:T})$ that we are computing. The unknown "parameters" θ live in the space $\Theta = \mathbb{R}^{64} \times \mathcal{F}$, where $\mathcal{F}$ is an appropriate function space. The states $x_{1:T}$ live in the space $\mathbb{R}^{6 \times 1,000}$. Hence, $p(\theta, x_{1:T} \mid y_{1:T})$ is actually a rather complicated object for this example.

Using the PGAS sampler (with $N = 15$ particles), we construct a Markov chain $\{\theta[r], x_{1:T}[r]\}_{r=1}^{R}$ with $p(\theta, x_{1:T} \mid y_{1:T})$ as its stationary distribution. We run this Markov chain for $R = 25,000$ iterations, where the first 10,000 are discarded. The result is visualized in Figs. 1 and 2, where we plot the Bode diagram for the linear system and the static nonlinearity, respectively. In both figures we also provide the 99 % Bayesian credibility interval. MATLAB code for Bayesian identification of Wiener models is available from

The resonance peaks are accurately modeled, but the result is less accurate at low frequencies (likely due to a lack of excitation). The fact that the posterior mean is inaccurate at low frequencies is encoded in our estimate of the posterior distribution as shown by the credibility intervals.

In Figs. 1 and 2, we have visualized not only the posterior mean but also the uncertainty for the entire model. We could do this since the model is a linear dynamical system followed by a static nonlinearity. It would be most interesting if we

can come up with ways in which we could visualize the uncertainty inherent in general nonlinear dynamical systems.

Maximum Likelihood Solutions

Identifying the parameters θ in a general nonlinear SSM using maximum likelihood amounts to solving the optimization problem (3). This is a challenging problem for several reasons, for example, it requires the computation of the predictor density $p_\theta(y_t \mid y_{1:t-1})$. Furthermore, its gradient (possibly also its Hessian) is very useful in setting up an efficient optimization algorithm. There are no closed-form solutions available for these objects, forcing us to rely on approximations. The SMC methods briefly introduced in section "Sequential Monte Carlo" provide rather natural tools for this task, since they are capable of producing approximations where the accuracy is only limited by the available computational resources.

To establish a clear interface between the maximum likelihood problem (3) and the SMC methods, it has proven natural to make use of the expectation maximization (EM) algorithm (Dempster et al. 1977). The EM algorithm proceeds in an iterative fashion to compute ML estimates of unknown parameters θ in probabilistic models involving latent variables. The strategy underlying the EM algorithm is to exploit the structure inherent in the probabilistic model to separate the original problem into two closely linked problems. The first problem amounts to computing the so-called *intermediate quantity*

$$
\begin{aligned}
\mathcal{Q}(\theta, \theta') &\triangleq \int \log p_\theta(x_{1:T}, y_{1:T}) \\
&\quad p_{\theta'}(x_{1:T} \mid y_{1:T}) \mathrm{d}x_{1:T} \\
&= \mathrm{E}_{\theta'} \left[\log p_\theta(x_{1:T}, y_{1:T}) \mid y_{1:T} \right], \quad (11)
\end{aligned}
$$

where we have already made use of the fact that the latent variables in an SSM are given by the states. Furthermore, θ' denotes a particular value for the parameters θ. We can show that by choosing a new θ such that

$\mathcal{Q}(\theta, \theta') \geq \mathcal{Q}(\theta', \theta')$, the likelihood is either increased or left unchanged, i.e., $\ell_T(\theta) \geq \ell_T(\theta')$.

The EM algorithm now suggests itself in that we can generate a sequence of iterates $\{\theta^k\}_{k \geq 1}$ that guarantees that the log-likelihood is not decreased for increasing k by alternating the following two steps: (1) (Expectation) compute the intermediate quantity $\mathcal{Q}(\theta, \theta^k)$ and (2) (maximization) compute the subsequent iterate θ^{k+1} by maximizing $\mathcal{Q}(\theta, \theta^k)$ w.r.t. θ. This procedure is then repeated until convergence, guaranteeing convergence to a stationary point on the likelihood surface.

The FFBSi particle smoother offers an approximation of the joint smoothing density $p_{\theta'}(x_{1:T} \mid y_{1:T})$ according to (9), which inserted into (11) provides an approximative solution $\hat{\mathcal{Q}}^M(\theta, \theta')$ to the expectation step. In solving the maximization step, we typically want gradients of the intermediate quantity $\nabla_\theta \hat{\mathcal{Q}}^M(\theta, \theta')$. These can also be approximated using (9). The above development is summarized in Algorithm 2, providing a solution where the basic building blocks are themselves complex algorithms, an SMC algorithm for the E step and a nonlinear optimization algorithm for the M step. This means that we have the option of replacing the FFBSi particle smoother in step 2a with any other algorithm capable of producing estimates of the joint smoothing density. The family of PMCMC methods introduced in section "Bayesian Solutions" contains several highly interesting alternatives. A detailed account on Algorithm 2 is provided by Schön et al. (2011); see also Cappé et al. (2005).

Algorithm 2 EM for nonlinear system identification

1. **Initialization:** Set $k = 0$ and initialize θ^k.
2. **Expectation (E) step:**
   (a) Compute an approximation $\hat{p}_{\theta^k}^M(x_{1:T} \mid y_{1:T})$, for example, using an FFBSi sampler.
   (b) Calculate $\hat{\mathcal{Q}}^M(\theta, \theta^k)$.
3. **Maximization (M) step:** Compute

$$
\theta_{k+1} = \arg\max_\theta \hat{\mathcal{Q}}^M(\theta, \theta^k).
$$

4. Check termination condition. If satisfied, terminate; otherwise, update $k \to k + 1$ and return to step 2.

Finally, we mention Fisher's identity opening up yet another avenue for designing ML estimators using SMC approximations. Even if we are not interested in using EM when solving the nonlinear system identification problem, the intermediate quantity (11) is useful. The reason is provided via *Fisher's identity*,

$$\nabla_\theta \ell_T(\theta)\big|_{\theta=\theta'} = \nabla_\theta \mathcal{Q}(\theta, \theta')\big|_{\theta=\theta'}$$

$$= \int \nabla_\theta \log p_\theta(x_{1:T}, y_{1:T})\big|_{\theta=\theta'}$$
$$p_{\theta'}(x_{1:T} \mid y_{1:T}) \mathrm{d}x_{1:T},$$

which provides a means to compute approximations of the log-likelihood gradient. Hessian approximations are also available, but these are more involved. Hence, Fisher's identity opens up for direct use of any off-the-shelf gradient-based optimization method in solving (4).

Online Solutions

Online (also referred to as recursive or adaptive) identification refers to the problem where the parameter estimate is updated based on the parameter estimate at the previous time step and the new measurement. This is used when we are dealing with big data sets and in real-time situations. SMC offers interesting opportunities when it comes to deriving online solutions for nonlinear state- space models. The most direct idea is simply to make use of a gradient method

$$\theta_t = \theta_{t-1} + \gamma_t \nabla_\theta \log p_\theta(y_t \mid y_{1:t-1}),$$

where $\{\gamma_t\}$ is the sequence of step sizes. Fisher's identity (12) opens up for the use of SMC in approximating $\nabla_\theta \log p_\theta(y_t \mid y_{1:t-1})$ However, this leads to a rapidly increasing variance, something that can be dealt with by the so-called "marginal" Fisher identity; see Poyiadjis et al. (2011) for details.

An interesting alternative is provided by an online EM algorithm; see, e.g., Cappé (2011) for a solid introduction. The online EM approaches rely on the additive properties of the $\mathcal{Q}$-function. The area of online solutions via SMC is likely to grow in the future as there is a clear need motivated by the constantly growing data sets and there are also clear theoretical opportunities.

Summary and Future Directions

We have discussed how SMC samplers can be used to solve nonlinear system identification problems, by sketching both Bayesian and ML solutions. A common feature of the resulting algorithms is that they are (nontrivial) combinations of more basic algorithms. We have, for example, seen the combined use of a particle smoother and a nonlinear optimization solver in Algorithm 2 to compute ML estimates. As another example we have the class of PMCMC methods, where the basic building blocks are provided by SMC samplers and MCMC samplers. The use of SMC and MCMC methods for nonlinear system identification has only just started to take off, and it presents very interesting future prospects. Some directions for future research are as follows: (1) The family of PMCMC algorithms is rich and fast growing, with great potential for further developments. For example, its use in solving the state smoothing problem (i.e., computing $p(x_{1:T} \mid y_{1:T})$) is likely to provide better algorithms in the near future. (2) Related to this is the potential to design new particle smoothers capable of generating new particles also in the time-reversed direction. (3) There are open and highly relevant challenges when it comes to designing backward simulators for Bayesian nonparametric methods (Hjort et al. 2010). A key question here is how to represent the backward kernel $p(x_t \mid x_{t+1}, y_{1:t})$ in such nonparametric settings. (4) The use of Bayesian nonparametric models will open up interesting possibilities for hybrid system identification, since they allow us to systematically express and work with uncertainties over segmentations.

Nonlinear System Identification: An Overview of Common Approaches

Qinghua Zhang
Inria, Campus de Beaulieu, Rennes Cedex, France

Abstract

Nonlinear mathematical models are essential tools in various engineering and scientific domains, where more and more data are recorded by electronic devices. How to build nonlinear mathematical models essentially based on experimental data is the topic of this entry. Due to the large extent of the topic, this entry provides only a rough overview of some well-known results, from gray-box to black-box system identification.

Keywords

Black-box models; Block-oriented models; Gray-box models; Nonlinear system identification

Introduction

The wide success of linear system identification in various applications (Ljung 1999; ▶ System Identification: An Overview) does not necessarily mean that the underlying dynamic systems are

intrinsically linear. Quite often, linear system identification can be successfully applied to a nonlinear system if its working range is restricted to a neighborhood of some working point. Nevertheless, some advanced engineering systems may exhibit significant nonlinear behaviors under their normal working conditions, so do most biological or social systems. There is therefore an increasing demand on nonlinear dynamic system modeling theory. Nonlinear system identification is studied to partly answer this demand, when experimental data carry the essential information for modeling purpose.

Nonlinear system identification, compared to its linear counterpart, is a much more vast topic, as in principle a nonlinear model can be *any* description of a system which is not linear. For this reason, this entry provides only a rough overview of some well-known results.

An overview of the basic concepts of system identification can be found in ▶ System Identification: An Overview, notably the five basic elements to be taken into account in each application, among which the (nonlinear) model structures will be mainly focused on by this entry, as they represent the essential particularities of nonlinear system identification problems.

The various model structures used in nonlinear system identification are often classified by the level of available prior knowledge about the considered system: from *white-box* models to *black-box* models, via *gray-box* models. In principle, a white-box model is fully built from prior knowledge. Such a fully white-box approach is rarely feasible for complex systems because of insufficient prior knowledge or of intractable system complexity. Therefore, the system identification methods summarized in this entry concern gray-box and black-box models, for which experimental data play an essential role.

For ease of presentation, the main content of this entry will be restricted to the single-input single-output (SISO) case. The multiple-input multiple-output (MIMO) case will be discussed in the section "Multiple-Input Multiple-Output Systems" below.

Gray-Box Models

This section covers gray-box models, from the most to the least demanding ones in terms of prior knowledge.

Parametrized Physical Models

The dynamic behaviors of some engineering systems are governed by well-known physical laws, typically in the form of differential equations, possibly with unknown parameters. These parametrized physical equations can be used as gray-box models for system identification. In most situations, such a model can be written in the form of a vectorial first-order ordinary differential equation (ODE), known as *state equation,* and can be generally written as

$$\frac{dx(t)}{dt} = f(x(t), u(t); \theta) \qquad (1)$$

where t represents the time, $x(t)$ is the *state* vector, $u(t)$ the *input,* and $f(\cdot)$ a (nonlinear) function parametrized by the vector θ.

The observation on the system (typically with electronic sensors), referred to as the *output* and denoted by $y(t)$, is related to $x(t)$ and $u(t)$ through another known parametrized equation

$$y(t) = h(x(t), u(t); \theta) + v(t) \qquad (2)$$

where $v(t)$ represents the measurement error.

With digital electronic instruments, the input $u(t)$ and the output $y(t)$ are sampled at some discrete-time instants, say $t = \tau, 2\tau, 3\tau, \ldots, N\tau$ with some constant sampling period $\tau > 0$. For the sake of notation simplicity, let the sampling period $\tau = 1$ and assume ideal instantaneous samplers; then the sampled input-output data set is denoted by

$$Z^N = \{u(1), y(1), u(2), y(2), \ldots, u(N), y(N)\}. \qquad (3)$$

In some applications, data samples are made at irregular time instants. Some studies are particularly focused on system identification in this case (Garnier and Wang 2008).

The main remaining task of gray-box system identification is to estimate the parameter vector θ from the data set Z^N. The identification criterion is typically defined with the aid of an output predictor derived from the system model. A natural output predictor is simply based on the numerical solution of the state equation (1): for some given value of θ, initial state $x(0)$ and some assumed inter-sample behavior of the input $u(t)$ (e.g., with a zero order hold), the trajectory of $x(t)$, denoted by $\hat{x}(t|\theta)$, is computed with a numerical ODE solver, then the output prediction is computed as

$$\hat{y}(t|\theta) = h(\hat{x}(t|\theta), u(t); \theta). \qquad (4)$$

The parameter vector θ is typically estimated by minimizing the sum of squared prediction error $\varepsilon(t|\theta) = y(t) - \hat{y}(t|\theta)$. See ▶ System Identification: An Overview and Bohlin (2006) for more details.

The predictor based on the numerical solution of the state equation (1) (known as a *simulator*) may be in trouble if this equation with the given value of θ is unstable. Moreover, the state equation (1) may also be subject to some modeling error that should be taken into account in the output predictor. In such cases, the output predictor can be made with the aid of some nonlinear state observer (Gauthier and Kupka 2001) or some nonlinear filtering algorithm (Doucet and Johansen 2011).

Alternatively, sequential Monte Carlo (SMC) methods can also be applied to the identification of (small size) nonlinear state-space systems, typically assuming a discrete-time counterpart of the model described by Eqs. (1) and (2). See ▶ Nonlinear System Identification Using Particle Filters.

The gray-box approach is particularly useful in an engineering field when some software library of commonly used components is available. In this case, a system model can be built by connecting available component models. Nevertheless, the "connection" of the component models may introduce algebraic constraints through variables shared by connected components, leading to *differential algebraic equations* (DAE),

which are a wider class of dynamic system models than the abovementioned state-space models (▶ Modeling of Dynamic Systems from First Principles). For most dynamic systems, it is possible to avoid the DAE formulation by causality analysis, so that the connections between different system components are treated as information flow, instead of algebraic constraints. There exist also some theoretic studies on DAE system identifiability (Ljung and Glad 1994) and some recent developments on the identification of such systems (Gerdin et al. 2007).

Combined Physical and Black-Box Models

It may happen that, in a complex system, part of the components is well described by physical laws (possibly with available models from a software library), but some other components are not well studied. In this case, the latter components can be dealt with black-box models (or possibly empirical models). The entire model can be fitted to a collected data set Z^N, like in the case of the previous subsection.

Block-Oriented Models

Complex systems, notably those studied in engineering, are often made of a certain number of components; thus a system model can be built by connecting component models. In this sense, such component-based models could be said "block-oriented." In the system identification literature, the term *block-oriented model* is often used in a particular context (Giri and Bai 2010), where it is typically assumed that each component is either a *linear dynamic* subsystem or a *nonlinear static* one. Here, the term "static" means that the behavior of the component is memoryless and can be described by an algebraic equation. The study of system identification with such models is motivated by the fact that, when a controlled system is stabilized around a working point, its dynamic behavior can be well described by a linear model, but its actuators and sensors may exhibit significant nonlinear behaviors like saturation or dead zone. The choice of a particular block-oriented model structure depends on the prior knowledge about the underlying system,
Nonlinear System Identification: An Overview of Common Approaches, Fig. 1 Hammerstein system
Nonlinear System Identification: An Overview of Common Approaches, Fig. 2 Wiener system

with specific identification methods available for different model structures.

The most frequently studied block-oriented models for system identification concern the Hammerstein system and the Wiener system, each composed of two blocks, as illustrated, respectively, in Figs. 1 and 2.

Hammerstein System Identification

A SISO Hammerstein system is typically formulated as

$$x(t) = f(u(t)) \tag{5a}$$

$$
\begin{aligned}
y(t) &+ a_1 y(t-1) + \cdots + a_{n_a} y(t-n_a) \\
&= b_1 x(t-1) + \cdots + b_{n_b} x(t-n_b) \\
&+ v(t).
\end{aligned} \tag{5b}
$$

If the nonlinearity $f(\cdot)$ is expressed in the form of

$$f(u) = \sum_{l=1}^{m} \gamma_l \kappa_l(u) \tag{6}$$

with some chosen basis functions $\kappa_l(\cdot)$, then the identification problem amounts to fitting the model parameters γ_l, a_i, b_j to a collected data set Z^N. A well-known method is based on over-parametrization (Bai 1998): replace in (5b) each $x(t-j)$ with the right-hand side of (6) and treat each parameter product $b_j \gamma_l$ as an individual parameter, then the newly parametrized model is equivalent to a linear ARX model (▶ System Identification: An Overview), which can be estimated by a well-established linear system identification method. As the $n_b + m$ parameters b_j and γ_l; are replaced by $n_b m$ parameters in the new parametrization, the term "over-parametrization" refers to the fact that typically $n_b + m < n_b m$. The estimated over-parametrized model can be reduced to the original parametrization, usually through the singular value decomposition (SVD) of the matrix filled with the estimated parameter products $b_j \gamma_l$. See Giri and Bai (2010) for other identification methods with variant formulations of Hammerstein system model.

When the linear subsystem is approximated by a finite impulse response (FIR) model, it is possible to first estimate the linear model before estimating a model for the nonlinear block (Greblicki and Pawlak 1989).

Wiener System Identification

A SISO Wiener system is typically formulated as

$$z(t) = \sum_{k=1}^{\infty} h_k u(t-k) \tag{7a}$$

$$y(t) = g(z(t)) + v(t) \tag{7b}$$

where the sequence $h_1, h_2, \ldots$ is the impulse response of the linear subsystem, $g(\cdot)$ is some nonlinear function, and $v(t)$ is a noise independent of the input $u(t)$.

Some methods for Wiener system identification assume a finite impulse response (FIR) of the linear subsystem. In this case, the linear subsystem model is characterized by the vector collecting the FIR coefficients $h^T = [h_1, h_2, \ldots, h_n]$. There are two typical kinds of efficient solutions, assuming either the Gaussian distribution of the input $u(t)$ (Greblicki 1992) or the monotonicity of the nonlinear function $g(\cdot)$ (Bai and Reyland Jr 2008). In both cases, it is possible to directly estimate the FIR coefficients h from the input-output data Z^N, without explicitly estimating the unknown nonlinear function $g(\cdot)$. The estimated h can be used to compute the internal variable $z(t)$. It then becomes relatively easy to estimate the nonlinear function $g(\cdot)$ from the computed $z(t)$ and the measured $y(t)$.

Other Block-Oriented Model Structures

Among block-oriented models composed of more blocks, the most well-known ones concern Hammerstein-Wiener system and Wiener-Hammerstein system. They are both composed of 3 blocks connected in series, the former has a linear dynamic block preceded and followed by two nonlinear static blocks, and the latter has a nonlinear static block in the middle of two linear dynamic blocks. In general, the prediction error method (PEM) (Ljung 1999) is applied to the identification of such systems, with heuristic methods for the initialization of model parameters. Some recent results on Hammerstein-Wiener system identification have been reported in Wills et al. (2013). There exist also some other variants, with parallel blocks or feedback loops. In most cases, each block is either *linear dynamic* or *nonlinear static,* but there is a notable exception: *hysteresis* blocks. Hysteresis is a phenomenon typically observed in some magnetic or mechanic systems. Its mathematical description is both dynamic and strongly nonlinear and cannot be decomposed into linear dynamic and nonlinear static blocks. Due to the importance of hysteresis components in some control systems, system identification involving such blocks is currently an active research topic (Giri et al. 2008).

LPV Models

Linear parameter-varying (LPV) models could be classified as black-box models, because typically they rely more on experimental data than on prior knowledge. However, engineers often have good insights into such models; they are thus presented in the gray-box section.

From Gain Scheduling to LPV Models

Gain scheduling is a method originally developed for the control of nonlinear systems. It consists in designing different controllers for different working points of a nonlinear system and in switching among the designed controllers according to the actual working point. It is typically assumed that the working point is determined by some observed variable (vector) referred to as the *scheduling variable* and denoted by ρ. Around

each considered working point, the nonlinear system is linearized so that the corresponding controller can be designed from the linear control theory. A by-product of this controller design procedure is a collection of linearized models indexed by the scheduling variable ρ. This collection, seen as a whole model of the globally nonlinear system, is known as an LPV model (Toth 2010). This approach has been particularly successful in the field of flight control.

An LPV model can be formulated either in input-output form or in state-space form. In the input-output form, a SISO model can be written as

$$y(t) + a_1(\rho) y(t-1) + \cdots + a_{n_a}(\rho) y(t - n_a)$$
$$= b_1(\rho) u(t-1) + \cdots + b_{n_b}(\rho) u(t - n_b)$$
$$+ v(t). \tag{8}$$

and in the state-space form as

$$x(t+1) = A(\rho) x(t) + B(\rho) u(t) + w(t) \tag{9a}$$

$$y(t) = c(\rho) x(t) + D(\rho) u(t) + v(t) \tag{9b}$$

As a global model of the whole nonlinear system, the ρ-dependent parameters (matrices) $a_i(\rho), b_j(\rho), A(\rho)$, etc., are functions defined for all $\rho \in \Omega$, where Ω is the relevant working range of the considered system (a compact subset of a real vector space). If originally the LPV model was built through a collection of linearized models around different working points, then the values of these functions are first defined for the corresponding discrete values of ρ. For other values of $\rho \in \Omega$, these functions can be defined by interpolation. Alternatively, by choosing some parametric forms of $a_i(\rho), b_j(\rho), A(\rho)$, etc., the whole LPV model can also be estimated by fitting it to a data set Z^N, through nonlinear optimization (Toth 2010).

Local Linear Models

In an LPV model, the model parameters can in principle depend on the scheduling variable ρ in

any chosen manner. A particularly useful case is when they are formulated as expansions over local basis functions. For example, in (8), the parameter $a_i(\rho)$ may be expressed as

$$a_i(\rho) = \sum_{l=1}^{m} a_{i,l}\kappa_l(\rho) \qquad (10)$$

where $k_l(\cdot)$ are some chosen bell-shaped (local) basis functions, typically the Gaussian function, centered at different positions $\rho = c_{l,} \in \Omega$, and $a_{i,l}$ are coefficients of the expansion. Similarly

$$b_j(\rho) = \sum_{l=1}^{m} b_{i,l}\kappa_l(\rho). \qquad (11)$$

Assume that the basis functions are normalized such that

$$\sum_{l=1}^{m} \kappa_l(\rho) = 1 \qquad (12)$$

for all $\rho \in \Omega$. Then the LPV model (8) can be viewed as an interpolation of m "local" models

$$y(t) + a_{1,l}y(t-1) + \cdots + a_{n_a,l}y(t-n_a)$$
$$= b_{1,l}u(t-1) + \cdots + b_{n_b,l}u(t-n_b) + v(t) \qquad (13)$$

indexed by $l = 1, 2, \ldots, m$. Each of these linear models is valid for ρ close to c_l, the center of the corresponding basis function $\kappa_l(\cdot)$; hence, they are called *local linear models*.

If the local basis functions $\kappa_l(\rho)$ are viewed as *membership functions* of fuzzy sets, then the local linear model is strongly related to the Takagi-Sugeno fuzzy model (Takagi and Sugeno 1985). An advantage of this point of view is the possibilities of incorporating prior knowledge in the form of linguistic rules and of interpreting some local linear models resulting from system identification.

There are two approaches to building local linear models. The first one is the local approach: for each chosen value of $c_{l,} \in \Omega$, a local model is estimated from data corresponding to the values of ρ within a neighborhood of c_l. This approach has the advantages of being computationally efficient, easily updatable, and well understood by engineers. The second one

is the global approach: all the model parameters are estimated simultaneously by solving a single optimization problem for the whole model. This approach can produce more accurate models in terms of prediction error, but it is numerically much more expensive and may lead to models difficult to be interpreted by engineers.

The practical success of local linear models strongly depends on the possibility of finding a scheduling variable ρ of small dimension relevantly determining the working point of the considered system. If there exists a nonlinear state-space model of the system, then in principle the working point is determined jointly by the state and the input of the system. As quite often physically meaningful state variables are not fully observed, they cannot be used in the definition of ρ. It is possible to define ρ as delayed output and input variables, e.g.,

$$\rho^T = [y(t), \ldots, y(t-n_a), u(t-1), \ldots, u(t-n_b)]$$

but it typically leads to a vector of quite large dimension. It is thus important to use practical insights about a given system to find a relevant vector ρ of reduced dimension.

For a single-dimensional ρ, the choice of the local basis function centers c_l can be made following some practical insight or equally spaced within Ω. For a large-dimensional ρ, this task is more difficult. The equally spaced approach would lead to too many local models, as their number would exponentially increase with the dimension of ρ. In this case, an empirical approach, called *local linear model tree* (LOLIMOT) (Nelles 2001), can be applied. It iteratively partitions Ω in order to place the local basis functions where the system is more likely nonlinear or where the available data are more concentrated.

Black-Box Models

Ideally speaking, a black-box model should be solely built from experimental data, without any prior knowledge. In practice, some prior knowledge is always necessary, though experimental

data play a much more important role. For instance, the choice of the input and output variables, implying some causality relationship, is an important prior knowledge.

With the fast development of electronic devices, more and more sensor signals are available in various fields, notably for engineering, environmental, and biomedical systems. Meanwhile, the processing power of modern computers increases every year. Black-box modeling has thus more and more potential applications. Nevertheless, the importance of prior knowledge in a modeling procedure should not be forgotten. In general prior knowledge leads to more reliable models in terms of validity range, as the validity of physical equations is often well understood. In contrast, for a black-box model essentially based on experimental data, it may be hard to ensure its validity for interpolation and even harder for extrapolation.

Input-Output Black-Box Models

As the primary role of a mathematical model is to predict the output of the system for given input values, it is natural to design black-box models directly in the form of a predictor. As the output $y(t)$ of a dynamic system depends on the past inputs, a predicted output $\hat{y}(t)$ may be formulated in the form of

$$\hat{y}(t) = f(u(t-1), u(t-2), \ldots, u(t-n_b)) \tag{14}$$

where $f(\cdot)$ is some nonlinear function (to be estimated from experimental data) and n_b is a chosen integer. In principle, n_b can be infinitely large (as $y(t)$ depends on *all* the past inputs in general), but in practice, a model of finite complexity has to be chosen. If the considered system is stable in the sense that sufficiently old past inputs are (gradually) forgotten, then it is reasonable to truncate the dependence on the past inputs.

The model structure (14) is similar to the linear finite impulse response (FIR) model (Ljung 1999). It is known that, for linear system identification, the use of ARX models, predicting $y(t)$ from both past inputs and past outputs, is often

more efficient than FIR models, in the sense of requiring fewer model parameters. By analogy, the nonlinear ARX model takes the form

$$\hat{y}(t) = f(y(t-1), \ldots, y(t-n_a),$$
$$u(t-1), \ldots, u(t-n_b)). \tag{15}$$

This is likely the most frequently used black-box model structure for nonlinear dynamic system identification (Sjöberg et al. 1995; Juditsky et al. 1995).

Nonlinear Function Estimators

For a nonlinear ARX model in the form of (15), the nonlinear function $f(\cdot)$ has to be estimated from an available input-output data set Z^N. Typically, an estimator of $f(\cdot)$ with some chosen parametric structure is used. Let

$$\phi^T(t) = [y(t-1), \ldots, y(t-n_a),$$
$$u(t-1), \ldots, u(t-n_b)], \tag{16}$$

then system identification in this case amounts to solving a nonlinear regression problem

$$y(t) = g(\phi(t); \theta) + v(t) \tag{17}$$

where $g(\cdot)$ is a chosen nonlinear function parametrized by θ, capable of approximating a large class of nonlinear functions by appropriately adjusting θ, and $v(t)$ is the modeling error to be minimized in some sense.

The most well-known nonlinear function estimators implementing $g(\cdot)$ in practice are polynomials, splines, multiple-layer neural networks, radial basis networks, wavelets, and fuzzy-neural estimators. Most of these estimators can be written in the form

$$g(\phi(t); \theta) = \sum_{l=1}^{m} \gamma_l \kappa(\alpha_l(\phi - \beta_l)) \tag{18}$$

or in some close variant of this form, where $\kappa(\cdot)$ is some "mother" basis function dilated and translated by α_l and β_l before being weighted by γ_l in the sum forming the estimator (Sjöberg et al. 1995). For example, $\kappa(\cdot)$ is

typically chosen as a (Gaussian) bell-shaped function in radial basis networks or a sigmoid (S-shaped) function in multiple-layer neural networks.

Another approach to nonlinear function estimation is called *nonparametric estimation.* Its main idea is to estimate $f(\varphi^*)$ for any given value of φ^* by the (weighted) average of the values of $y(t)$ in the available data set corresponding to values of $\varphi(t)$ close to φ^*. This category includes *kernel* estimators (Nadaraya 1964) and *memory-based* estimators (Specht 1991).

The nonlinear function estimation problem as formulated in (17) can also be addressed with the Gaussian process model. Assume that g in (17) is a Gaussian process whose covariance matrix for any regressor pair $\varphi(t)$ and $\varphi(\tau)$ is a known function of the regressor pair, then the posterior distribution of g given observations on $y(t)$ can be computed by applying the Bayes' theorem under certain assumptions (Rasmussen and Williams 2006). This method is strongly related to the least squares support vector machines (Suykens et al. 2002) and to some extent is similar to kernel estimators.

The difficulty for estimating a nonlinear function $f(\varphi)$ strongly depends on the dimension of φ. In the single-dimensional case, most existing methods can produce satisfactory results. When the dimension of φ, say n, increases, in order to keep the data "density" unchanged, the number of data points must increase exponentially with n. This fact implies that, in the high-dimensional case (say $n > 10$), for most practically available data sets, the data points are sparse in the space of φ. It is thus practically impossible to estimate $f(\varphi)$ with a good accuracy everywhere in the space of φ. In order to remedy this problem, prior knowledge can be used to form a more elaborated vector φ of reduced dimension, instead of the simple form of past input and output variables. The resulting model will be more of gray-box nature. If this approach is not possible, one has to expect that the estimation algorithm automatically discovers some low-dimension nature of the nonlinear relationship being estimated. The success would depend on the suitability of the

chosen particular nonlinear function estimator for the considered system.

State-Space Black-Box Models

For a gray-box model in the form of (1) and (2), it is assumed that the parametric forms of the nonlinear functions $f(\cdot)$ and $h(\cdot)$ are known from prior knowledge. If no such knowledge is available, it is possible to estimate these nonlinear functions with some function estimator, like those introduced in the previous subsection. Such an approach leads to state-space black-box models. In practice, it is easier to use the discrete-time counterpart of the state equation (1). Because typically the state vector $x(t)$ is not directly observed, the estimation of $f(\cdot)$ and $h(\cdot)$ cannot be formulated as nonlinear regression problems, in contrast to the case of input-output black-box models. Another difficulty is related to the nonuniqueness of the state-space representation of a given system: any (linear or nonlinear) state transformation would lead to a different state-space representation of the same system. In some existing methods, a linear state-space model is first estimated; then nonlinear function estimators are used to compensate the residuals of $f(\cdot)$ and $h(\cdot)$ after their linear approximations (Paduart et al. 2010).

Multiple-Input Multiple-Output Systems

For multiple-input multiple-output (MIMO) systems, state-space models like (1)–(2) remain in the same form, by considering vector values of the notations $u(t)$ and $y(t)$ at each time instant, up to some similar adaptation of the other involved notations. For input-output models like (15), the involved notations can also be vector valued, but the fact that different inputs and/or outputs can have different delays makes the notations more complicated. For block-oriented models, though a MIMO linear block is usually described by a general linear model in state-space form or in input-output form, there is no consensus for the structural choice of MIMO nonlinear blocks.

Some Practical Issues

The general practical aspects discussed in ▶ System Identification: An Overview are of course also valid for nonlinear system identification, but some particularities in the nonlinear case should be highlighted.

It is important to apply appropriate input signals so that the collected data convey sufficient information for system identification. The design of input signals for this purpose is known as *experiment design*. In the framework of linear system identification, experiment design is usually formulated through the optimization of the covariance matrix of model parameter estimates (▶ Experiment Design and Identification for Control), which often leads to non-convex optimization problems. Experiment design in the nonlinear case has not been systematically studied. If possible, the chosen input signal should be similar to what will be actually applied to the considered system and cover various working conditions. Another simple rule is that the input should excite a nonlinear system at different amplitudes, whereas binary input signals are often used for linear systems.

Model validation is a particularly delicate task for nonlinear black-box models. As already mentioned when such models are introduced, the available data points are usually sparse when a nonlinear function is estimated in a high-dimensional space; it is thus practically impossible to uniformly ensure the estimation accuracy of the nonlinear function. It is important to extensively perform *cross-validation,* by testing the validity of the model on large data sets that have not been used for model estimation.

Regularization is also an important issue for nonlinear black-box models. Because of lack of prior knowledge, each nonlinear black-box model has a flexible structure in order to cover a large class of nonlinear systems, typically with many model parameters, implying large variances of parameter estimates (▶ System Identification: An Overview). Appropriately applying a regularized criterion for model parameter estimation can reduce the variances. For gray-box models, prior knowledge can be used for regularization through a Bayesian approach, but this approach is not applicable to black-box models.

Summary and Future Directions

Compared to linear system identification, the nonlinear case is a much more vast topic, of which this entry provides only a rough overview. The main lines that should be retained are that both prior knowledge and experimental data are required for system identification and that the more prior knowledge is incorporated in a model, the better the extent of its validity is understood. The lack of prior knowledge should be compensated by the processing of large amounts of data. The data that can be processed within an acceptable time depend on the power of computers that progresses every year. Meanwhile, the research and development of efficient algorithms for large data processing with multiple or massively parallel processors are an exciting topic in system identification.

Nonlinear Zero Dynamics

Alberto Isidori

Abstract

The notion of zero dynamics plays a role in nonlinear systems that is analogous to the role played, in a linear system, by the notion of zeros of the transfer function. In this article, we review the basic concepts underlying the definition of zero dynamics and discuss its relevance in the context of nonlinear feedback design.

Keywords

High-gain feedback; Inverse systems; Minimum-phase nonlinear systems; Normal forms; Output regulation; Stabilization

Introduction

The concept of zero dynamics of a nonlinear system was introduced in the early 1980s as the nonlinear analogue of the concept of transmission zero of a linear system. This concept played a fundamental role in the development of systematic methods for asymptotic stabilization of

relevant classes of nonlinear systems. As a matter of fact, a nonlinear system in which the zero dynamics possess a globally asymptotically stable equilibrium can be robustly stabilized, globally or at least with guaranteed region of attraction, by means of output feedback. This is a nonlinear analogue of a well-know property of linear systems, namely, the property that an n-dimensional linear systems having $n - 1$ zeros with negative real part can be stabilized by means of proportional output feedback, if the feedback gain is sufficiently large. The concept of zero dynamics also plays a relevant role in variety of other problems of feedback design, such as input-output linearization with internal stability, non-interacting control with internal stability, output regulation, and feedback equivalence to passive systems.

The Zero Dynamics

One of the cornerstones of the geometric theory of control systems (for linear as well as for nonlinear systems) is the analysis of how the observability property can be influenced by feedback. This study, originally conceived in the context of the problem of disturbance decoupling, had far reaching consequences in a number of other domains. One of these consequences is the possibility of characterizing in "geometric terms" the notion of *zero* of the transfer function of a system. In a (single-input single-output and minimal) linear system, a complex number z is a zero of the transfer function if and only if the input $u(t) = \exp(zt)$ yields – for a suitable choice of the initial state – a forced response in which the output is identically zero. This "open-loop" and "time-domain" characterization has a "closed-loop and "geometric" counterpart: all such z's coincide with the eigenvalues of the unobservable part of the system, once the latter has been rendered maximally unobservable by means of feedback. One of the earlier successes of the geometric approach to the analysis and design of nonlinear systems was the possibility of extending these equivalent characterizations to the domain of nonlinear systems.

To see how this is possible, consider for simplicity the case of a system modeled by equations of the form

$$
\begin{aligned}
\dot{x} &= f(x) + g(x)u \\
y &= h(x)
\end{aligned}
$$

with state $x \in \mathbb{R}^n$, input $u \in \mathbb{R}$, output $y \in \mathbb{R}$ and in which $f(x), g(x), h(x)$ are smooth functions. Systems of this forms are called *input-affine systems*. The analysis of such systems is rendered particularly simple if appropriate notations are used. Given any real-valued smooth function $\lambda(x)$ and any n-vector valued smooth function $X(x)$, let $L_X \lambda(x)$ denote the (directional) derivative of $\lambda(x)$ along $X(x)$, that is the real-valued smooth function

$$
L_X \lambda(x) = \sum_{i=1}^{n} \frac{\partial \lambda}{\partial x_i} X_i(x) ,
$$

and, recursively, set $L_X^d \lambda = L_X L_X^{d-1} \lambda(x)$ for any $d \geq 1$.

Suppose there exists an integer $r \geq 1$ with the following properties

$$
L_g h(x) = L_g L_f h(x) = \cdots = L_g L_f^{r-2} h(x)
$$

$$
= 0 \quad \forall x \in \mathbb{R}^n
$$

$$
L_g L_f^{r-1} h(x) \neq 0 \qquad \forall x \in \mathbb{R}^n .
$$

If this is the case, it is possible to show that the set

$$
Z^* = \{x \in \mathbb{R}^n : h(x) = L_h(x) = \cdots
$$

$$
= L_f^{r-1} h(x) = 0\}
$$

is a smooth sub-manifold of $\mathbb{R}^n$, of codimension r. It is also easy to show that the state-feedback law

$$
u^*(x) = -\frac{L_f^r h(x)}{L_g L_f^{r-1} h(x)}
$$

renders the vector

$$
f^*(x) = f(x) + g(x)u^*(x)
$$

tangent to Z^*, at each point x of Z^*. In other words, Z^* is an *invariant* manifold of the feedback-modified system

$$\dot{x} = f^*(x).$$

It is seen from this construction that the output $y(t) = h(x(t))$ of the system is identically zero if and only if $x(0) \in Z^*$ and $u(t) = u^*(x(t))$, where $x(t)$ is the solution of $\dot{x} = f^*(x)$ passing through $x(0)$ at time $t = 0$. As a consequence, the *restriction* of $\dot{x} = f^*(x)$ to its invariant manifold Z^* characterizes all *internal* dynamics that occur in the system once initial condition and input are chosen in such a way that the output is constrained to be identically zero. The dynamics in question are called the *zero-dynamics* of the system. Note that this construction demonstrates, as anticipated, the equivalence between an "open-loop" and a "closed-loop" characterization of all the (internal) dynamics of a given system that are compatible with the constraint that the output is identically zero. This construction can be extended to multi-input multi-output systems, with the aid of an appropriate recursive algorithm, known as the *zero dynamics algorithm* (Isidori 1995).

Normal Forms

The coordinate-free construction presented above becomes even more transparent if special coordinates are chosen. To this end, set

$$g^*(x) = \frac{1}{L_g L_f^{r-1} h(x)} g(x)$$

and define, recursively,

$$X_0(x) = g^*(x), \quad X_k(x) = [f^*(x), X_{k-1}(x)],$$

for $1 \le k \le r-1$, in which $[Y(x), X(x)]$ denotes the Lie bracket of $Y(x)$ and $X(x)$. It is possible to show that if the vector fields $X_0(x), \dots, X_{n-1}(x)$ are *complete*, there exists a smooth nonlinear, *globally defined*, change of variables by means of which the system can be transformed into a system of the form

$$\dot{z} = f_0(z, \xi)$$
$$\dot{\xi} = A_r \xi + B_r [q_0(z, \xi) + b(z, \xi)u]$$
$$y = C_r \xi$$

in which $z \in \mathbb{R}^{n-r}$, $\xi \in \mathbb{R}^n$, the matrices A_r, B_r, C_r have the form

$$A_r = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ 0 & 0 & 0 & \cdots & 1 \\ 0 & 0 & 0 & \cdots & 0 \end{pmatrix}, \quad B_r = \begin{pmatrix} 0 \\ 0 \\ \cdots \\ 0 \\ 1 \end{pmatrix},$$

$$C_r = \begin{pmatrix} 1 & 0 & 0 & \cdots & 0 \end{pmatrix},$$

and $b(z, \xi) \ne 0$ for all (z, ξ). These equations are said to be in *normal form* (Isidori 1995).

It is easy to check that, in these coordinates, the manifold Z^* is the set of all pairs (z, ξ) having $\xi = 0$, the state feedback law $u^*(x)$ is the function

$$u^*(z, \xi) = -\frac{q_0(z, \xi)}{b(z, \xi)}$$

and the restriction of $\dot{x} = f^*(x)$ to the manifold Z^* is nothing else than

$$\dot{z} = f_0(z, 0).$$

The latter provide a simple characterization of the zero dynamics of the system, once that the latter has been brought to its normal form.

It is worth observing that, in the case of a linear system, functions $f_0(z, \xi)$ and $q_0(z, \xi)$ are linear functions, and $b(z, \xi)$ is a constant. Consequently, the normal form can be written as

$$\dot{z} = Fz + G\xi$$
$$\dot{\xi} = A_r \xi + B_r [Hz + K\xi + bu]$$
$$y = C_r \xi.$$

It is also easy to check that the transfer function of the system can be expressed as

$$T(s) = b \frac{\det(sI - F)}{\det(sI - A)},$$

in which

$$A = \begin{pmatrix} F & G \\ B_r H & A_r + B_r K \end{pmatrix}.$$

From this it is concluded that in a (controllable and observable) linear system, the zeros of the transfer function $T(s)$ coincide with the eigenvalues of F. In other words, in a linear system the zero dynamics are linear dynamics whose eigenvalues coincide with the zeros of the transfer function of the system.

The Inverse System

Another property associated with the notion of zero of the transfer function, in a (single-input single-output) linear system, is the fact that the zeros characterize the dynamics of the inverse system (the latter being – loosely speaking – a system able to reproduce the input $u(t)$ from output $y(t)$ that this input has generated). This property has an immediate analogue for nonlinear systems. Considering system in normal form and setting

$$\mathbf{y}^{r-1}(t) = \mathrm{col}(y(t), y^{(1)}(t), \dots, y^{(r-1)}(t)),$$

it is easily seen that the input $u(t)$ can be determined as the output of a dynamical system, driven by $\mathbf{y}^{r-1}(t)$ and $y^{(r)}(t)$, modeled by

$$\begin{aligned} \dot{z} &= f_0(z, \mathbf{y}^{r-1}) \\ u &= \frac{y^{(r)} - q_0(z, \mathbf{y}^{r-1})}{b(z, \mathbf{y}^{r-1})}. \end{aligned} \qquad (1)$$

Thus, it is concluded that the unforced internal dynamics of the inverse system coincide with the zero dynamics as defined above.

It should be stressed, though, that the coincidence is limited to the case of single-input single-output systems. For a multi-input multi-output nonlinear systems, the link between zero dynamics and the dynamics of the inverse system is more subtle. This is essentially due to the fact that while the concept of zero dynamics only seeks to determine the dynamics compatible with

the constraint that the output is identically zero, the inverse system must describe all dynamics resulting in *any* admissible output function. As a consequence, computation of the zero dynamics and computation of the inverse system (whenever this is possible) are not equivalent and the latter is possible only under substantially stronger assumptions. The computation of the zero dynamics is based on an extension (Isidori 1995) of the classical algorithm of Wonham (1979) for the computation of the largest controlled invariant subspace in the kernel of the output map, while the computation of the inverse system is based on extensions, due to Hirschorn (1979) and Singh (1981) of the so-called structure algorithm introduced by Silverman (1969) for the computation of inverses and zero structure at the infinity. For a comparison of such assumptions and of their influence on the outcome of the associated algorithms, see Isidori and Moog (1988).

Input-Output Linearization

An appealing feature of the normal form described above is the straightforward observation that a (state) feedback law of the form

$$u = \frac{1}{b(z, \xi)}[-q_0(z, \xi) + K_r \xi + v]$$

changes the system into a system

$$\begin{aligned} \dot{z} &= f_0(z, \xi) \\ \dot{\xi} &= (A_r + B_r K_r)\xi + B_r v \\ y &= C_r \xi \end{aligned}$$

whose input-output behavior (between input v and output y) is *fully linear* (and stable if K_r is chosen so that the matrix $A_r + B_r K_r$ in Hurwitz). In fact, the law in question renders the system partially unobservable, with all nonlinearities confined to its unobservable part (Isidori et al. 1981). This control law is clearly non-robust, as it relies upon exact cancelation of possibly uncertain terms, but it can be rendered robust by means of appropriate dynamic compensation (Freidovich and Khalil 2008).

The system obtained in this way has the structure of a cascade of two sub-systems, one of which, modeled as

$$\dot{z} = f_0(z, \xi),$$

is seen as "driven" by the input ξ. This motivates the interest in classifying the asymptotic properties of such subsystem, as discussed below.

Asymptotic Properties of the Zero Dynamics

Linear systems with no zeroes in the right-half complex plane are traditionally called *minimum-phase* systems, in view of certain properties of the Bode gain and phase plots of its transfer function. Thus, in view of the interpretation given above, linear systems whose zero dynamics are asymptotically stable are minimum-phase systems. This terminology has been (somewhat abusively, but with the clear intent of providing a concise and expressive characterization) borrowed to classify nonlinear systems whose zero dynamics have desirable (from the stability viewpoint) properties. Assuming that $z = 0$ is an equilibrium of $\dot{z} = f_0(z, 0)$, the following cases are considered:

- A nonlinear system is *locally minimum-phase* (respectively, *locally exponentially minimum-phase*) if the equilibrium $z = 0$ of $\dot{z} = f_0(z, 0)$ is locally asymptotically (respectively locally exponentially) stable (Byrnes and Isidori 1984).
- A nonlinear system is *globally minimum-phase* if the equilibrium $z = 0$ of $\dot{z} = f_0(z, 0)$ is globally asymptotically stable (Byrnes and Isidori 1991).
- A nonlinear system is *strongly minimum-phase* if the system $\dot{z} = f_0(z, \xi)$, viewed as a system with input ξ and state z, is input-to-state stable (Liberzon 2002).

According to the well-known criterion of Sontag (1995) for input-to-state stability, a system is strongly minimum phase if and only if there exists a positive definite and proper smooth real-valued function $V(z)$, class $\mathcal{K}_{\infty}$

functions $\underline{\alpha}(\cdot), \overline{\alpha}(\cdot), \alpha(\cdot)$ and a class $\mathcal{K}$ function $\chi(\cdot)$ satisfying

$$\underline{\alpha}(|z|) \leq V(z) \leq \overline{\alpha}(|z|) \qquad \forall z$$
$$\frac{\partial V}{\partial z} f_0(z, \xi) \leq -\alpha(|z|) \quad \forall (z, \xi)$$
$$\text{such that } |z| \geq \chi(|\xi|).$$

As a special case, it is seen that a system is globally minimum phase if and only if there exists a function $V(z)$, bounded as above, such that

$$\frac{\partial V}{\partial z} f_0(z, 0) \leq -\alpha(|z|) \qquad \forall z.$$

If, instead, the weaker inequality

$$\frac{\partial V}{\partial z} f_0(z, 0) \leq 0 \qquad \forall z$$

holds, the system is said to be *globally weakly minimum-phase*.

The criterion summarized above is of paramount importance in the design of feedback laws to the purpose of stabilizing nonlinear systems that are globally (or strongly) minimum phase, as it will be seen below.

Zero Dynamics and Stabilization

The first and foremost immediate implication of the properties described above is the fact that the feedback law

$$u = \frac{1}{b(z, \xi)}[-q_0(z, \xi) + K_r \xi],$$

if K_r is chosen so that the matrix $A_r + B_r K_r$ in Hurwitz, globally asymptotically stabilizes the equilibrium $(z, \xi) = (0, 0)$ of a strongly minimum-phase system. In fact, as observed, the corresponding closed-loop system can be seen as an asymptotically stable (linear) system driving an input-to-state stable (nonlinear) system. As already observed, this control mode is non-robust (as it relies upon exact cancelations) and requires the availability of the full state (z, ξ) of the controlled system. However, both these

deficiencies can be to some extent fixed, by means of appropriate techniques, that will be briefly reviewed below.

If the requirement of global stability is replaced by the (weaker) requirement of *stability with a guaranteed region of attraction*, then the desired control goal can be achieved by means of a much simpler law, depending only on the partial state ξ and not requiring cancelations. Stability with a guaranteed region of attraction essentially means that a given equilibrium is rendered asymptotically stable, with a region of attraction that contains an a priori *fixed* compact set. In this context, the most relevant results can be summarized as follows.

Assume the system possesses a globally defined normal form and, without loss of generality, let $b(z, \xi) > 0$. Let the system be controlled by a "partial state" feedback of the form

$$u = -kK_r\xi\,,$$

in which $k \in \mathbb{R}$. Under this control mode, the following results are obtained:

- Suppose the system is strongly minimum phase. Then, there is a matrix K_r and, for every choice of a compact set $\mathcal{C}$ and of a number $\varepsilon > 0$, there are a number k^* and a time T^* such that, if $k \geq k^*$, all trajectories of the closed-loop system with initial condition in $\mathcal{C}$ are bounded and satisfy $|x(t)| \leq \varepsilon$ for all $t \geq T^*$.

- Suppose the system is strongly minimum phase and also locally exponentially minimum phase. Suppose $q_0(0, 0) = 0$. Then, there is a matrix K_r and, for every choice of a compact set $\mathcal{C}$ there is a number k^* such that, if $k \geq k^*$, the equilibrium $x = 0$ of the system is locally asymptotically stable, with a domain of attraction that contains the set $\mathcal{C}$.

In these results, the system is stabilized by means of a *static* control law that depends only on the partial state ξ and not on the (possibly unknown) quantities $q_0(z, \xi)$, $b(z, \xi)$. Bearing in mind the fact that the r components of ξ coincide with the output y and its derivatives $y^{(1)}, \ldots, y^{(r-1)}$, it is possible to replace the

control in question by means of a *dynamic* control law that only depends on the output y, following a design paradigm originally proposed by H. Khalil. In fact, if the system is strongly minimum phase and also locally exponentially minimum phase and if $q_0(0, 0) = 0$, asymptotic stability with a guaranteed region of attraction can be achieved by means of dynamical feedback law of the form Khalil and Esfandiari (1993)

$$\begin{aligned}
\dot{\hat{\xi}}_1 &= \hat{\xi}_2 + \kappa c_{r-1}(y - \hat{\xi}_1)\\
\dot{\hat{\xi}}_2 &= \hat{\xi}_3 + \kappa^2 c_{r-2}(y - \hat{\xi}_1)\\
&\quad\cdots\\
\dot{\hat{\xi}}_{r-1} &= \hat{\xi}_r + \kappa^{r-1} c_1(y - \hat{\xi}_1)\\
\dot{\hat{\xi}}_r &= \kappa^r c_0(y - \hat{\xi}_1)\\
u &= -\sigma_L(kK_r\hat{\xi})\,,
\end{aligned}$$

in which κ and the c_i are design parameters and $\sigma_L(s)$ is a smooth saturation function, characterized as follows: $\sigma_L(s) = s$ if $|s| \leq L$, $\sigma_L(s)$ is odd and monotonically increasing, with $0 < \sigma_L'(s) \leq 1$, and $\lim_{s\to\infty} \sigma_L(s) = L(1 + c)$ with $0 < c \ll 1$. The number L is a design parameter also.

It is also possible to show that a suitable "extension" of this dynamic feedback law can be used to asymptotically recover the effects of the input-output linearizing law considered earlier. In this way, the lack of robustness intrinsically present in such control law is overcome (Freidovich and Khalil (2008)).

Output Regulation

The concept of zero dynamics plays a fundamental role in the problem of output regulation. The problem in question considers a controlled plant modeled by

$$\begin{aligned}
\dot{x} &= f(w, x, u)\\
e &= h(w, x)\,,
\end{aligned}$$

in which u is the control input, w is a set of exogenous variables (command and disturbances),

and e is a set of regulated variables. The exogenous variables are thought of as generated by an autonomous system

$$\dot{w} = s(w)$$

known as the *exosysten*. The problem is to design a (possibly dynamic) controller

$$\dot{x}_c = f_c(x_c, e)$$
$$u = h_c(x_c, e)$$

driven by the regulated variable e, such that in the resulting closed-loop system all trajectories are ultimately bounded and $\lim_{t \to \infty} e(t) = 0$. The problem in question has been the object of intensive research in the past years. In what follows we limit ourselves to highlight the role of the concept of zero dynamics in this problem.

Assume that the set W where the exosystem evolves is compact and invariant and suppose a controller exists that solves the problem of output regulation. Then, the associated closed-loop has a steady-state locus (see Isidori and Byrnes 2008), the graph of a possibly set-valued map defined on W. Suppose the map in question is single-valued, which means that for each given exogenous input function $w(t)$, there exists a *unique* steady-state response, expressed as $x(t) = \pi(w(t))$ and $x_c(t) = \pi_c(w(t))$. If, in addition, $\pi(w)$ and $\pi_c(w)$ are continuously differentiable, it is readily seen that

$$L_s \pi(w) = f(w, \pi(w), \psi(w))$$
$$0 = h(w, \pi(w))$$
$$L_s \pi_c(w) = f_c(\pi_c(w), 0) \qquad \forall w \in W.$$
$$\psi(w) = h_c(\pi_c(w), 0)$$

The first two equations, introduced in Isidori and Byrnes (1990), are known as the *nonlinear regulator equations*. They clearly show that the graph of the map $\pi(w)$ is a manifold contained in the zero set of the output map e, rendered invariant by the control $u = \psi(w)$. In particular, the steady-state trajectories of the closed-loop system are trajectories of the *zero dynamics* of

the controlled plant. The second two equations, on the other hand, interpret the ability, of the controller, to generate the feedforward input necessary to keep $e(t) = 0$ in steady-state. This is a nonlinear version of the well-known *internal model principle* of Francis and Wonham (1975).

Passivity

Consider a nonlinear input-affine system having the same number m of inputs and outputs and recall that this system is said to be *passive* if there exists a continuous nonnegative function real-valued function $W(x)$, with $W(0) = 0$, that satisfies

$$W(x(t)) - W(x(0)) \leq \int_0^t y^T(s)u(s)ds$$

along trajectories. The function $W(x)$ is the so-called *storage function* of the system.

It is well known that the notion of passivity plays an important role in system analysis and that the theory of passive systems leads to powerful methodologies for the design of feedback laws for nonlinear systems. In this context, the question of whether a given, non-passive, nonlinear system could be rendered passive by means of state feedback is indeed relevant. It turns out that this possibility can be simply expressed as a property of the zero dynamics of the system.

Suppose that $L_g h(x)$ is nonsingular and set $g^*(x) = g(x)[L_g h(x)]^{-1}$. If the m columns of $g^*(x)$ are complete and commuting vector fields, there exists a globally defined change of coordinates that brings the system in normal form

$$\dot{z} = f_0(z, y)$$
$$\dot{y} = q_0(z, y) + b(z, y)u$$

Then, there exists a feedback law $u = \alpha(z, y)$ that renders the resulting closed-loop system passive, with a C^2 and positive definite storage function $W(x)$, if and only if the system is globally weakly minimum phase (Byrnes et al. 1991).

Limits of Performance

It is well-known that linear systems having zeros in the left-half plane are difficult to control, and obstruction exists to the fulfillment of certain control specifications. One of these is found in the analysis of the so-called *cheap control problem*, namely, the problem of finding a stabilizing feedback control that minimizes the functional

$$J_\varepsilon = \frac{1}{2} \int_0^\infty [y^{\mathrm{T}}(t)y(t) + \varepsilon u^{\mathrm{T}}(t)u(t)]dt$$

when $\varepsilon > 0$ is small. As $\varepsilon \to 0$, the optimal value J_ε^* tends to J_0^*, the *ideal performance*. It is well-known that, in a linear system, $J_0^* = 0$ if and only if the system is minimum phase and right invertible and, in case the system has zeros with positive real part, it is possible to express explicitly J_0^* in terms of the zeros in question. If the (linear) system is expressed in normal form as

$$\dot{z} = Fz + G\xi$$
$$\dot{\xi} = Hz + K\xi + bu$$
$$y = \xi$$

with $b \neq 0$, and the zero dynamics are antistable (that is *all* the eigenvalues of F have positive real part), it can be shown that J_0^* coincides with the minimal value of the energy

$$J = \frac{1}{2} \int_0^\infty \xi^{\mathrm{T}}(t)\xi(t)dt$$

required to stabilize the (antistable) system $\dot{z} = Fz + G\xi$. In other words, the limit as $\varepsilon \to 0$ of the optimal value of J_ε is equal to the least amount of energy required to stabilize the dynamics of the inverse system.

This result has an appealing nonlinear counterpart (Seron 1999). In fact, for a nonlinear input-affine system having the same number m of inputs and outputs in normal form, with $f_0(z, \xi)$ of the form $f_0(z, \xi) = f_0(z) + g_0(z)\xi$ and $\dot{z} = f_0(z)$ antistable, under appropriate technical assumptions (mostly related to the existence of the solution of the associated optimal control problems), the same result holds: the lowest attainable

value of the L_2 norm of the output coincides with the least amount of energy required to stabilize the dynamics of z.

Summary and Future Directions

The concept of zero dynamics plays an important role in a large number of problems arising in analysis and design of nonlinear control systems, among which the most relevant ones are the problems of asymptotic stabilization and those of asymptotic tracking/rejection of exogenous command/disturbance inputs. Essentially, all such applications deal with single-input single-output systems, require the system to be preliminarily reduced to a special form by means of appropriate change of coordinates, and assume the dynamics in question to be globally asymptotically stable. The analysis of systems having many inputs and many outputs, of systems in which normal forms cannot be defined, and of systems in which the zero dynamics are unstable is still a challenging and unexplored area of research.

Nonparametric Techniques in System Identification

Rik Pintelon and Johan Schoukens
Department ELEC, Vrije Universiteit Brussel, Brussels, Belgium

Abstract

This entry gives an overview of classical and state-of-the-art nonparametric time and frequency-domain techniques. In opposition to parametric methods, these techniques require no detailed structural information to get insight into the dynamic behavior of complex systems. Therefore, nonparametric methods are used in system identification to get an initial idea of the model complexity and for model validation purposes (e.g., detection of unmodeled dynamics). Their drawback is the increased variability compared with the parametric estimates. Although the main focus of this entry is on the classical identification framework (estimation of dynamical systems operating in open loop from known input, noisy output observations), the reader will also learn more about (i) the connection between transient and leakage errors, (ii) the estimation of dynamical systems operating in closed loop, (iii) the estimation in the presence of input noise, and (iv) the influence of nonlinear distortions on the linear framework. All results are valid for discrete- and continuous-time systems. The entry concludes with some user choices and practical guidelines for setting up a system identification experiment and choosing an appropriate estimation method.

Keywords

Best linear approximation; Correlation method; Empirical transfer function estimate; Errors-in-variables; Feedback; Frequency response function; Gaussian process regression; Impulse transient response modeling method; Local polynomial method; Local rational method; Noise (co)variances; Noise power spectrum; Spectral analysis

Introduction

Nonparametric representations such as frequency response functions (FRFs) and noise power spectra are very useful in system identification: they are used (i) to verify the quality of the identification experiment (high or poor signal-to-noise ratio?), (ii) to get quickly insight into the dynamic behavior of the plant (complex or easy identification problem?), and (iii) to validate the

parametric plant and noise models (detection of unmodeled dynamics); see also ▶ System Identification: An Overview. In addition, via specially designed periodic excitation signals, it is possible to detect and quantify the nonlinear distortions in the FRF estimate. As such, without estimating a parametric model, the users can easily decide whether or not the linear framework is accurate enough for their particular application.

The estimation of the nonparametric models typically starts from sampled input-output signals $u(nT_s)$ and $y(nT_s), n = 0, 1, \ldots, N - 1$, that are transformed to the frequency domain via the discrete Fourier transform (DFT)

$$X(k) = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} x(nT_s) e^{-j2\pi kn/N} \quad (1)$$

with T_s the sampling period, $x = u$ or y, and $X = U$ or Y. One of the main difficulties in estimating an FRF and noise power spectrum is the leakage error in the DFT spectrum $X(k) = \text{DFT}(x(t))$ (1). It is due to the finite duration NT_s of the experiment, and it increases the mean square error of the nonparametric estimates. Therefore, all methods try to suppress the leakage error as much as possible.

This entry starts by a detailed analysis of the leakage problem (section "The Leakage Problem"), followed by an overview of standard and advanced nonparametric time (section "Nonparametric Time-Domain Techniques") and frequency (section "Nonparametric Frequency-Domain Techniques") domain techniques. First, it is assumed that the system operates in open loop (see Fig. 1) and that known input, noisy output observations are available (sections "Nonparametric Time-Domain Techniques" and "Nonparametric Frequency-Domain Techniques"). Next, section "Extensions" extends the results to systems operating in closed loop (section "Systems Operating in Feedback"); to noisy input, noisy output observations (section "Noisy Input, Noisy Output Observations"); and to nonlinear systems (section "Nonlinear Systems"). Finally, some user choices are discussed (section "User Choices") and
Nonparametric Techniques in System Identification, Fig. 1 Classical identification framework: discrete- or continuous-time plant operating in open loop; known input $u(t)$, noisy output $y(t)$ observations; and $v(t)$ filtered discrete-time or band-limited continuous-time white noise $e(t)$ that is independent of $u(t)$. $y_0(t)$ denotes the true output of the plant. In the continuous-time case, it is assumed that the unobserved driving noise source $e(t)$ has finite variance and constant (*white*) power spectrum within the acquisition bandwidth

some practical guidelines are given (section "Guidelines"). Unless otherwise stated, the input $u(t)$ and the disturbing noise $v(t)$ are assumed to be statistically uncorrelated.

The Leakage Problem

For arbitrary excitations $u(t)$, the relationship between the true input $U(k)$ and true output $Y_0(k)$ DFT spectra (1) of a linear dynamic system is given by

$$Y_0(k) = G(\Omega_k)U(k) + T_G(\Omega_k) \quad (2)$$

where $\Omega_k = j\omega_k$ or $\exp(-j\omega_k T_s)$ for, respectively, continuous- and discrete-time systems; $\omega_k = 2\pi k/(NT_s)$; $G(\Omega_k)$ the plant frequency response function; and $T_G(\Omega_k)$ the leakage error due to the plant dynamics (Pintelon and Schoukens 2012, Section 6.3.2). The leakage error $T_G(\Omega)$ is a smooth function of the frequency that decreases to zero as $O(N^{-1/2})$ for N increasing to infinity. It depends on the difference between the initial and final conditions of the experiment and has exactly the same poles as the plant transfer function. Therefore, the

time-domain response of $T_G(\Omega)$ is decaying exponentially to zero as a transient error.

From this short discussion, it can be concluded that the leakage error in the frequency domain is equivalent to the transient error in the time domain. The only difference being that the former depends on the difference between the initial and final conditions, while the latter solely depends on the initial conditions.

Standard spectral analysis methods (see section "Spectral Analysis Method") suppress the leakage term $T_G(\Omega_k)$ in (2) by multiplying the time-domain signals with a window $w(t)$ before taking the DFT (1)

$$(X(k))W = \frac{1}{\sqrt{N}\,w_{\mathrm{rms}}} \sum_{n=0}^{N-1} w(nT_s)x(nT_s)e^{-j2\pi\frac{kn}{N}} \tag{3}$$

with $w_{\mathrm{rms}} = \left(\sum_{n=0}^{N-1} |w(nT_s)|^2 / N\right)^{1/2}$ the root mean square (rms) value of the window $w(t)$. The scaling in (3) is such that the transformation preserves the rms value of the signal. The relationship between the DFT spectra $(U(k))_W$ and $(Y_0(k))_W$ of the windowed input-output signals $w(t)u(t)$ and $w(t)y_0(t)$ is given by

$$(Y_0(k))W = G(\Omega_k)\,(U(k))_W + E_{\mathrm{int}}(k) + E_{\mathrm{leak}}(k) \tag{4}$$

where $E_{\mathrm{int}}(k)$ and $E_{\mathrm{leak}}(k)$ are, respectively, the interpolation error and the remaining leakage error

$$E_{\mathrm{int}}(k) = (G(\Omega_k)U(k))_W - G(\Omega_k)\,(U(k))_W \tag{5}$$

$$E_{\mathrm{leak}}(k) = (T_G(\Omega_k))_W \tag{6}$$

Note that $E_{\mathrm{int}}(k) = 0$ if $G(\Omega_k)$ is constant within the bandwidth of $W(k)$, while the interpolation error is large if the FRF varies significantly within the window bandwidth. To keep $E_{\mathrm{int}}(k)$ small, the frequency resolution $1/(NT_s)$ should be sufficiently large and the window bandwidth should be small enough. On the other hand, a larger window bandwidth is beneficial for reducing the leakage error $E_{\mathrm{leak}}(k)$. Hence, choosing an appropriate window for nonparametric FRF

and noise power spectrum estimation is making a trade-off between the reduction of the leakage error $E_{\mathrm{leak}}(k)$ and the increase of the interpolation error $E_{\mathrm{int}}(k)$ (Schoukens et al. 2006).

Note that exactly the same analysis can be made for the continuous- or discrete-time dynamics of the disturbing output noise $v(t)$ in Fig. 1

$$V(k) = H(\Omega_k)E(k) + T_H(\Omega_k) \tag{7}$$

with $H(\Omega_k)$ the noise frequency response function, $E(k)$ the DFT of the unobserved driving discrete-time or band-limited continuous-time white noise source $e(t)$ (Pintelon and Schoukens 2012, Section 6.7.3), and $T_H(\Omega_k)$ the noise leakage (transient) term. The noise leakage term is often neglected but can be important for lightly damped systems (e.g., in modal analysis). Most nonparametric techniques suppress the sum of the plant and noise leakage errors $T_G(\Omega_k) + T_H(\Omega_k)$.

If an integer number of periods of the steady-state response to a periodic excitation is measured, then the plant leakage error $T_G(\Omega_k)$ in (2) is zero, which simplifies significantly the estimation problem. Therefore, for the frequency-domain techniques, a distinction is made between periodic and nonperiodic excitations. Note, however, that the noise leakage (transient) term $T_H(\Omega_k)$ in (7) remains different from zero.

Nonparametric Time-Domain Techniques

The time-domain methods estimate the impulse response of the plant via the time-domain relationship that the true output $y_0(t)$ equals the convolution product between the impulse response $g(t)$ and the true input $u(t)$. For discrete-time systems, it takes the form

$$y_0(t) = \sum_{n=0}^{\infty} g(n)u(t-n) \tag{8}$$

In practice only a finite number of impulse response coefficients $g(t)$ can be estimated from

N input-output samples, and, therefore, (8) is approximated by a finite sum

$$y_0(t) \approx \sum_{n=0}^{L} g(n)u(t-n) \qquad (9)$$

where $L \leq N - 1$ should also be determined from the data. From (9), it can be seen that the response depends on the past input values $u(-1), u(-2), \ldots, u(-L)$. Since these values are unknown, an exponentially decaying transient error is present in the first L samples of the predicted output (9). This transient error is the time-domain equivalent of the leakage error $T_G(\Omega_k)$ in (2). To remove the transient error, the first L output samples can be discarded in the predicted output (9). It reduces the amount of data from N to $N - L$ and, hence, increases the mean square error of the estimates. If it is known that the transfer function has no direct term, then $g(0) = 0$, and the sum (9) starts from $n = 1$.

Correlation Methods

Correlation methods have been studied intensively since the end of the 1950s (see Eykhoff 1974) and are nowadays still used in telecommunication channel estimation and equalization. The impulse response coefficients are found by minimizing the sum of the squared differences between the observed output samples and the output samples predicted by (9)

$$\sum_{t=L}^{N-1} \left(y(t) - \sum_{n=0}^{L} g(n)\, u(t-n) \right)^2 \qquad (10)$$

w.r.t. $g(m), m = 0, 1, \ldots, L$. The solution of this linear least squares problem is given by the famous Wiener-Hopf equation

$$\hat{R}_{yu}(m) = \sum_{n=0}^{L} g(n)\, \hat{R}_{uu}(m-n) \qquad (11)$$

for $m = 0, 1, \ldots, L$, where $\hat{R}_{yu}$ and $\hat{R}_{uu}$ are estimates of, respectively, the cross- and autocorrelation functions $R_{yu}(\tau) = \mathbb{E}\{y(t)u(t-\tau)\}$ and $R_{uu}(\tau) = \mathbb{E}\{u(t)u(t-\tau)\}$

$$\hat{R}_{yu}(m) = \frac{1}{N-L} \sum_{t=L}^{N-1} y(t)u(t-m) \qquad (12)$$

$$\hat{R}_{uu}(m-n) = \frac{1}{N-L} \sum_{t=L}^{N-1} u(t-n)u(t-m) \qquad (13)$$

(Godfrey 1993, Chapter 1; Ljung 1999, Chapter 6). Since the number of estimated impulse response coefficients L can grow with the amount of data N, the correlation method (11) is classified as being nonparametric. If the input is white noise, then the expected value of $\hat{R}_{uu}(m)$ is proportional to the Kronecker delta $\delta(m)$, and the cross-correlation $\hat{R}_{yu}(m)$ (11) is – within a scaling factor – a good approximation of the impulse response. This property is used in blind channel estimation.

Gaussian Process Regression

The linear least squares (10) solution can be (very) sensitive to disturbing output noise if L is not much smaller than N. This problem is circumvented by the Gaussian process regression approach. The key idea consists in modeling the impulse response coefficients $g(n)$ as a zero-mean Gaussian process with a certain covariance structure P_L that depends on a few hyper-parameters (Pillonetto et al. 2011). In Chen et al. (2012), it has been shown that the Gaussian process regression is equivalent to the following regularized (see also ▶ System Identification Techniques: Convexification, Regularization, and Relaxation) linear least squares problem

$$\sum_{t=L}^{N-1} \left(y(t) - \sum_{n=0}^{L} g(n)u(t-n) \right)^2 + \sigma^2 g^T P_L^{-1} g \qquad (14)$$

where $g = (g(0), g(1), \ldots, g(L))^T$ and with σ^2 the variance of the output disturbance. The hyper-parameters defining P_L and the noise variance σ^2 are estimated via an empirical Bayes method.

Nonparametric Frequency-Domain Techniques

The frequency-domain techniques estimate the frequency response function (FRF) using relationship (2) or (4) between the input-output DFT spectra. We start with the simplest approach and gradually increase the complexity of the estimation methods. Note that nonparametric FRF estimation is still a quickly evolving research area, such that the pros and cons of the advanced methods are yet not well established.

Empirical Transfer Function Estimation

If an integer number of periods P of the steady-state response to a *periodic excitation* is observed, then the leakage term in $T_G(\Omega_k)$ in (2) is zero, and the FRF is estimated by dividing the output by the input DFT spectra at the *excited frequencies* (Pintelon and Schoukens 2012, Section 2.4)

$$\hat{G}(\Omega_k) = \frac{Y(k)}{U(k)} \qquad (15)$$

The output noise variance $\sigma_V^2(k)$ is estimated via the sample variance $\hat{\sigma}_V^2(k)$ of the output DFT spectra over the P consecutive signal periods. The variance of the FRF estimate (15) is then given by

$$\text{var}(\hat{G}(\Omega_k)) = \frac{\sigma_V^2(k)}{P\,|U(k)|^2} \qquad (16)$$

where $|U(k)|$ is the magnitude of $U(k)$.

Applying (15) to *random excitations* gives the empirical transfer function estimate (Ljung 1999, Section 6.3). Due to the presence of the plant leakage error $T_G(\Omega_k)/U(k)$, the statistical properties of (15) for random inputs are quite different from those for periodic inputs. While the empirical transfer function estimate (ETFE) is unbiased and has finite variance (16) for periodic inputs, it is biased and has infinite variance for random inputs (Broersen 2004). To improve the statistical properties of the ETFE for random inputs, one can either approximate locally the ETFE by a polynomial (Stenman et al. 2000) or perform a weighted average of ETFEs over

subrecords of the total response (Ljung 1999, Section 6.4). In Heath (2007), it is shown that the optimally (in mean square sense) weighted ETFE equals the spectral analysis method.

Spectral Analysis Method

The spectral analysis method is available in any digital spectrum analyzer. It is based on the relationship between the FRF and the cross- and autopower spectra of the input-output signals

$$G(\Omega) = \frac{S_{yu}(\Omega)}{S_{uu}(\Omega)} = \frac{F\{R_{yu}(\tau)\}}{F\{R_{uu}(\tau)\}} \qquad (17)$$

with $F\{\}$ the Fourier transform (Bendat and Piersol 1980, Chapter 4; Brillinger 1981, Chapter 8). Comparing (11) and (17), it can be seen that the spectral analysis method is the frequency-domain equivalent of the correlation method (take the Fourier transform of the expected value of (11)). There are basically two methods for estimating the cross- and autopower spectra in (17) from sampled data: the Blackman and Tukey (1958) and the Welch (1967) procedures.

The Blackman-Tukey procedure (Blackman and Tukey 1958; Ljung 1999, Section 6.4) consists in taking the DFT (3) of the windowed cross- and autocorrelation functions, viz.,

$$\hat{R}_{yu}(\tau) = \frac{1}{N} \sum_{t=}^{N-1} y(t)\, u(t - \tau) \qquad (18)$$

$$\hat{S}_{Ryu}(k) = \frac{1}{\sqrt{N}} \sum_{\tau=0}^{N-1} w(\tau)\, \hat{R}_{yu}(\tau) e^{-j2\pi \frac{k\tau}{N}} \quad (19)$$

resulting in an FRF estimate (17) at the full frequency resolution $1/(NT_s)$ of the measurement. It can be shown that (19) is a smoothed version of the periodogram $Y(k)\overline{U(k)}$, where is $\bar{U}$ the complex conjugate of U (Brillinger 1981, Chapter 5).

In the Welch approach (Welch 1967; Pintelon and Schoukens 2012, Section 2.6), the N input-output samples are split into M subrecords of N/M samples each, and the DFT spectra $(U^{[m]}(k))_W$ and $(Y^{[m]}(k))_W$ of the windowed

input and output samples are calculated via (3) where N is replaced by N/M, giving

$$\hat{S}_{Y_W U_W}(k) = \frac{1}{M} \sum_{m=1}^{M} \left(Y^{[m]}(k)\right) W \overline{\left(U^{[m]}(k)\right) W} \tag{20}$$

$$\hat{S}_{U_W U_W}(k) = \frac{1}{M} \sum_{m=1}^{M} \left|\left(U^{[m]}(k)\right) W\right|^2 \tag{21}$$

The spectral analysis estimate of the FRF and its variance are then given by

$$\hat{G}(\Omega_k) = \frac{\hat{S}_{Y_W U_W}(k)}{\hat{S}_{U_W U_W}(k)} \tag{22}$$

$$\mathrm{var}(\hat{G}(\Omega_k)) \approx \frac{\sigma_V^2(k)}{M} \mathbb{E}\left\{\hat{S}_{U_W U_W}^{-1}(k)\right\} \tag{23}$$

(Brillinger 1981, Chapter 8; Heath 2007). Finally, the output noise variance $\sigma_V^2(k)$ in (23) is estimated as

$$\hat{\sigma}_V^2(k) = \frac{M}{M-1}\left(\hat{S}_{Y_W Y_W}(k) - \frac{\left|\hat{S}_{Y_W U_W}(k)\right|^2}{\hat{S}_{U_W U_W}(k)}\right) \tag{24}$$

(Brillinger 1981, Chapter 8; Pintelon and Schoukens 2012, Section 2.5.4). Due to the spectral width of the window used, the estimates (22) and (24) are correlated over the frequency (the correlation length is about twice the spectral width). Note that (21) is used for estimating noise power spectra (Brillinger 1981, Chapter 5). Note also that for *periodic excitations* combined with a rectangular window $w(nT_s) = 1$, the spectral analysis estimate (22), where each subrecord is equal to a signal period, simplifies to the ETFE (15).

Compared with the Blackman-Tukey procedure (19), the FRF estimate (22) based on the Welch approach (20) and (21) has a frequency resolution and a variance (23) that are M times smaller. In measurement devices, the FRFs are estimated using the Welch approach (20)–(22) where each subrecord is an independent measurement with a fixed number of samples. The reason for this is that the cross- and autopower spectra estimates (20) and (21) can easily be updated as

more experiments (input-output data records) are available. If the number of measured records M increases to infinity, then (22) converges to the true value, provided a perfect suppression of the leakage error.

In measurement devices, the quality of the spectral analysis estimate (22) is often quantified via the coherence $\gamma^2(\omega)$

$$\gamma^2(\omega) = \frac{\left|S_{yu}(\Omega)\right|^2}{S_{yy}(\Omega) S_{uu}(\Omega)} \tag{25}$$

which is comprised between 0 and 1. It is related to the variance of the spectral analysis estimate as

$$\mathrm{var}(\hat{G}(\Omega_k)) = \frac{1 - \gamma^2(\omega_k)^2}{\gamma}(\omega_k) \left|G(\Omega_k)\right|^2$$

A coherence smaller than 1 indicates the presence of disturbing noise, residual leakage errors, nonlinear distortions, or a nonobserved input.

Following the same lines of Welch (1967), the statistical properties of the spectral analysis estimate (22) can be improved via overlapping subrecords in the cross- and autopower spectra estimates (20) and (21). This has been studied in detail for noise power spectra in Carter and Nuttall (1980) and for FRFs in Antoni and Schoukens (2007).

Advanced Methods

The goal of the advanced methods is to estimate the FRF at the full frequency resolution $1/(NT_s)$ of the experiment duration NT_s while suppressing the influence of the leakage and the noise errors. Without some extra information, it is impossible to achieve this goal via (2). The additional piece of information that allows one to solve the problem is that the FRF and the leakage error are locally smooth functions of the frequency.

The *local polynomial method* (Pintelon and Schoukens 2012, Chapter 7) approximates the FRF and the leakage error in (2) locally in the frequency band $[k - n, k + n]$ by a polynomial. From the residuals of the local linear least squares solution, one also gets an estimate of the output noise variance σ_V^2 and, hence, also of the variance of the FRF. The whole procedure is repeated for

all DFT frequencies k in the frequency band of interest. The correlation length of the estimates equals $\pm 2n$, which is twice the local bandwidth of the polynomial approximation.

The *local rational method* (McKelvey and Guérin 2012) follows the same lines as the local polynomial method, except that the FRF and the leakage error in (2) are locally approximated by rational forms with the same poles ($G = B/A$ and $T_G = I/A$). Due to the common poles, the local rational approximation problem can be transformed into a local linear least squares problem. The method is biased but suppresses better the plant leakage error of lowly damped systems.

The *transient impulse response modeling method* (Hägg and Hjalmarsson 2012) approximates the FRF and the leakage error by, respectively, finite impulse and transient response models, giving a large sparse global linear least squares problem. From the residuals of the global linear least squares solution, one gets an estimate of the output noise variance σ_V^2 and, hence, also of the variance of the FRF. This approach has the best smoothing properties and is recommended in case the noise error is dominant.

Extensions

In sections "Nonparametric Time-Domain Techniques" and "Nonparametric Frequency-Domain Techniques," it is assumed that the linear plant operates in open loop and that the input is known exactly. If the plant operates in feedback and/or the input observations are noisy, then the presented time and frequency-domain techniques are biased. In sections "Systems Operating in Feed-

back" and "Noisy Input, Noisy Output Observations," it is shown that the estimation bias can be avoided if a known external reference signal is available (typically the signal stored in the arbitrary waveform generator).

Since most real-life systems behave to some extent nonlinearly, it is important to detect and quantify the nonlinear effects in FRF estimates. This issue is handled in section "Nonlinear Systems."

Systems Operating in Feedback

The key difficulty of estimating the FRF of a plant operating in feedback (see Fig. 2) using *nonperiodic excitations* is that the true input $u(t)$ is correlated with the process noise $v(t)$. The direct approaches of sections "Nonparametric Time–Domain Techniques" and "Nonparametric Frequency-Domain Techniques" lead to biased estimates (Wellstead 1981). This can easily be seen from the ETFE (15) applied to the feedback setup in Fig. 2

$$\hat{G}(\Omega_k) = \frac{G(\Omega_k)G_{\text{act}}(\Omega_k)R(k) + V(k)}{G_{\text{act}}(\Omega_k)R(k) - G_{\text{fb}}(\Omega_k)V(k)} \quad (26)$$

where $G_{\text{act}}(\Omega_k)$ and $G_{\text{fb}}(\Omega_k)$ are, respectively, the actuator and feedback dynamics. From (26), it follows that in those frequency bands where the process noise $V(k)$ dominates, one rather estimates minus the inverse of the feedback dynamics instead of the plant FRF. On the other hand, at those frequencies where the reference signal injects most power, the ETFE (26) will be close to the plant FRF.
Nonparametric Techniques in System Identification, Fig. 2 Plant operating in closed loop: $r(t)$ is the external reference signal, the known input $u(t)$ depends on the process noise $v(t)$, and $y(t)$ is the noisy output observation
Nonparametric Techniques in System Identification, Fig. 3 Errors-in-variables framework: $r(t)$ is the external reference signal; $n_g(t)$ is the generator noise; $m_u(t)$, $m_y(t)$ are the input and output measurement errors; $v(t)$ is the process noise; and $u(t)$, $y(t)$ are the noisy input, noisy output observations

If a known external reference signal is available, then the bias is avoided via the indirect method proposed in Wellstead (1981)

$$G(\Omega) = \frac{S_{yr}(\Omega)/S_{rr}(\Omega)}{S_{ur}(\Omega)/S_{rr}(\Omega)} = \frac{S_{yr}(\Omega)}{S_{ur}(\Omega)}. \quad (27)$$

The basic idea consists in modeling the feedback setup (see Fig. 2) from the known reference to the input and output simultaneously. This reduces the single-input, single-output closed loop problem to a single-input, two-output open loop problem. Since the process noise $v(t)$ is independent of the reference signal $r(t)$, the direct estimate of the single-input, two-output FRF is unbiased. Calculating the ratio of the two FRFs finally gives the indirect estimate (27). This procedure can be applied to any of the direct methods of sections "Nonparametric Time-Domain Techniques" and "Nonparametric Frequency-Domain Techniques." Proceeding in this way, unstable plants operating in a stabilizing feedback loop can also be handled.

If the excitation is *periodic*, then the process noise $v(t)$ is independent of the periodic part of the input $u(t)$, and the ETFE (15) converges to the true value as the number of periods P tends to infinity (Pintelon and Schoukens 2012, Section 2.5). Hence, in the periodic case, no external reference is needed.

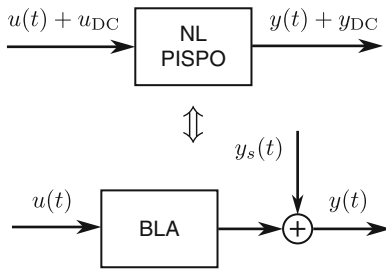
Noisy Input, Noisy Output Observations

The key difficulty of estimating the FRF of a plant excited by a *nonperiodic signal* from noisy input, noisy output observations (see Fig. 3) is that the input autopower spectrum in (17) is biased. Indeed, due to the noise on the input, $S_{uu}(\Omega)$ is too large, resulting in too small direct FRF estimates. This is true for all direct FRF approaches in sections "Nonparametric Time-Domain Techniques" and "Nonparametric Frequency-Domain Techniques." Applying the indirect method of section "Systems Operating in Feedback" removes the bias because the noise on the input is independent of the reference signal (e.g., see (27)). Proceeding in this way, the closed loop case (see Fig. 2) with noisy input, noisy output observations is also solved by the indirect method.

If the excitation is *periodic*, then the mean value of the input-output DFT spectra over the P consecutive periods converges to the their true values as P tends to infinity (Pintelon and Schoukens 2012, Section 2.5). Hence, the ETFE (15) is still consistent, and no external reference is needed. The same conclusion is valid for systems operating in feedback.

Nonlinear Systems

The classes of nonlinear systems considered are those systems whose steady-state response to a periodic input is periodic with the same period as the input. It excludes phenomena such as chaos and subharmonics but allows for hard nonlinearities such as saturation, dead zones, and clipping.

The classes of excitations considered are stationary random signals with a specified power spectrum and probability density function. An important special case is the class of


Nonparametric Techniques in System Identification, Fig. 4 Best linear approximation (*BLA*) of a nonlinear (*NL*) period in, same period out (*PISPO*) system, excited by a zero-mean random signal $u(t)$ with a given power spectrum and probability density function. $y(t)$ is the zero-mean part of the actual output of the nonlinear system. u_{DC} and y_{DC} are the DC levels of the actual input and output of the nonlinear system. The zero-mean output residual $y_s(t)$ is uncorrelated with – but not independent of – the input $u(t)$

Gaussian excitation signals with a specified power spectrum. This class includes random phase multisines (a sum of harmonically related sinewaves with user-specified amplitudes and random phases) with the same Riemann equivalent power spectrum (Pintelon and Schoukens 2012, Section 4.2).

Consider a nonlinear (NL) period in, same period out (PISPO) system excited by a random excitation belonging to a particular class (see Fig. 4). The FRF (17), where the expected value is taken w.r.t. the random realization of the excitation, is the best (in mean square sense) linear approximation (BLA) of the nonlinear PISPO system, because the difference $y_s(t)$ between the actual output of the nonlinear system (DC value excluded) and the output predicted by the linear approximation is uncorrelated with the input $u(t)$ (Enqvist and Ljung 2005). Although uncorrelated with the input, the output residual $y_s(t)$ still depends on $u(t)$. If the NL PISPO system operates in feedback (see Fig. 2), then the indirect method (27) is used for calculating the BLA, and the output residual $y_s(t)$ is uncorrelated with – but not independent of – the reference signal $r(t)$ (Fig. 2).

For the class of Gaussian excitation signals, it can be shown that the DFT spectrum $Y_S(k)$ of $y_s(t)$ has the following properties (Pintelon and Schoukens 2012, Section 3.4.4):

1. $Y_S(k)$ has zero-mean value: $\mathbb{E}\{Ys(k)\} = 0$.
2. $Y_S(k)$ it is uncorrelated with – but not independent of $-U(k) : \mathbb{E}\{Y(k)\overline{U(k)}\} = 0$.
3. $Y_S(k)$ is asymptotically ($N \to \infty$) normally distributed.
4. $Y_S(k)$ is asymptotically ($N \to \infty$) uncorrelated over the frequency.

These second-order properties are exactly the same as those of a filtered white noise disturbance, except that the noise is independent of the input. It shows that it is impossible to distinguish the nonlinear distortions $y_s(t)$ from the disturbing noise $v(t)$ in FRF measurements using stationary random excitations (only second-order statistics are involved in (22)–(24)).

Using random phase multisines, it is possible to detect and quantify the nonlinear distortions because $y_s(t)$ is then periodically related to the input $u(t)$ (property of the NL PISPO system). Indeed, analyzing the FRF over consecutive signal periods quantifies the noise variance $v(t)$ ($y_s(t)$ does not change over the periods), while analyzing the FRF over different random phase realizations of the input quantifies the sum of the noise variance and the variance of the nonlinear distortions ($y_s(t)$ depends on the random phase realization of the input). Subtracting both variances gives an estimate of the variance of the nonlinear distortions. While this variance quantifies exactly the variability of the nonparametric FRF estimate due to the nonlinear distortions, it can (significantly) underestimate the variability of a parametric plant model. The basic reason for this is that the true variance of the parametric plant model also depends on the nonzero higher (>2) order moments between the input $u(t)$ and the nonlinear distortions $y_s(t)$.

User Choices

There is no clear answer to the question which of the presented techniques is the best. It strongly depends on the intended use of the nonparametric estimates and the particular application handled. For example, the intended use can be:

1. A smooth representation of the FRF
2. Use of the nonparametric estimates as an intermediate step for parametric modeling of the plant

In the first case, one should opt for the minimum mean square error solution, while in the second case, it is crucial that the nonparametric estimates are unbiased, possibly at the price of an increased variance. Indeed, the parametric plant modeling step cannot eliminate the bias error in the nonparametric estimates while it suppresses the variance error.

The application-dependent answers to the following questions strongly influence the choice and the settings of the method used:

1. Is a large frequency resolution needed and/or is leakage the dominant error?
2. Is the noise or the leakage error dominant?
3. Is it necessary to detect and quantify the nonlinear behavior?

If the answer to the first question is yes, then one should opt for one of the advanced methods (section "Advanced Methods") or use the spectral analysis estimates (section "Spectral Analysis Method") with a small number M of subrecords. On the other hand, if the noise error is dominant, then M in (22)–(24) should be chosen as large as possible. To detect and quantify the nonlinear effects, one should use periodic signals (random phase multisines) combined with the ETFE (section "Empirical Transfer Function Estimation").

Finally, comparing the different nonparametric techniques is also not straightforward because of their different

1. Frequency resolution
2. Quality of the estimated noise model
3. Correlation length over the frequency

The latter is set by the spectral width of the window used in the spectral analysis method and the local bandwidth in the advanced methods.

Guidelines

While the previous sections give well-established facts about the different nonparametric techniques,

in this section, we provide some advices/guidelines based on our personal interpretation of these facts:

- Always store the reference signal together with the observed input-output signals. The knowledge of the reference signal allows one to solve nonparametrically the closed loop and errors-in-variables problems.
- Whenever possible use periodic excitation signals (random phase multisines): they allow one to estimate from one experiment the FRF, the noise level, and the level of the nonlinear distortions. As such the deviation of the true dynamic behavior from the ideal linear time-invariant framework is quantified.
- Select one of the advanced methods if frequency resolution is of prime interest.
- If the goal of the identification experiment is to minimize the prediction error, then the Gaussian process regression method is a very promising approach.
- For lowly damped systems and a limited frequency resolution, the local rational method is a good candidate solution.
- Use a minimum mean square solution for a smooth representation of the FRF.
- Choose unbiased nonparametric estimates for use in parametric plant modeling (estimation, validation, and model selection).
- When comparing nonparametric techniques, always take into account all aspects of the estimates: the bias and variance of the FRF and noise model, the frequency resolution, and the correlation length over the frequency.

Summary and Future Directions

Nonparametric techniques are very useful because they simplify the parametric plant modeling in the initial selection of the model complexity and in the detection of unmodeled dynamics. The classical correlation and spectral analysis methods developed in the 1950s and refined till the 1980s are still widely used. Recently, advanced time- and frequency-domain

methods have been developed which all try to minimize the sensitivity (bias and variance) of the nonparametric estimates to disturbing noise, nonlinear distortion, and transient (leakage) errors.

The renewed research interest in nonparametric techniques should be continued to handle the following challenging problems: short data sets, missing data, detection and quantification of time-variant behavior, modeling of time-variant dynamics, and modeling of nonlinear dynamics.

Numerical Methods for Continuous-Time Stochastic Control Problems

George Yin
Department of Mathematics, Wayne State University, Detroit, MI, USA

Abstract

This expository article provides a brief review of numerical methods for stochastic control in continuous time. It concentrates on the methods of Markov chain approximation for controlled diffusions. Leaving most of the technical details out with the broad general audience in mind, it aims to serve as an introductory reference or a user's guide for researchers, practitioners, and students who wish to know something about numerical methods for stochastic control.

Keywords

Markov chain approximation; Numerical methods; Stochastic control

Introduction

This expository article provides a brief review of numerical methods for stochastic control in continuous time. Leaving most of the technical details out with the broad general audience in mind, it aims to serve as an introductory reference for researchers, practitioners, and students, who wish to know something about numerical methods for stochastic controls.

The study of stochastic control has witnessed tremendous progress in the last few decades; see, for example, Fleming and Rishel (1975), Fleming and Soner (1992), Kushner (1977), and Yong and Zhou (1999) among others, for fundamentals of stochastic controls as well as historical remarks. Much of the development has been accompanied by the needs and progress in science, engineering, as well as finance. Typically, the problems are highly nonlinear, so a closed-form solution is very difficult to obtain. As a result, designing feasible numerical algorithms becomes vitally important. Among the many approximation methods, the Markov chain approximation methods have shown most promising features. Primarily for treating diffusions, the Markov chain approximation method was initiated in the 1970s (Kushner 1977) and substantially developed further in Kushner (1990b) and Kushner and Dupuis (1992). Nowadays, such method are used for more complex jump diffusions, or systems with random switchings. There were also efforts to incorporate the methods into an expert system so that the methods can be placed into an easily usable tool box (Chancelier et al. 1986, 1987). In addition to the existing applications in a wide variety of engineering problems, recently applications include such areas as insurance, quantile hedging for guaranteed minimum death benefits, dividend payment and investment strategies with capital injection, singular control, risk management, portfolio selection with bounded constraints, and production planning and manufacturing problems; see Jin et al. (2011, 2012, 2013), Sethi and Zhang (1994), and Yin et al. (2009) and references therein.

Let us begin with the controlled diffusion problem. We wish to minimize the cost function defined by

$$J(x, u(\cdot)) = E_x\left[\int_0^\tau R(X(t), u(t))dt + B(X(\tau))\right],$$
(1)

with the $\mathbb{R}^r$-valued process $X(t)$ defined by the solution of the stochastic differential equation

$$dX(t) = b(X(t), u(t))dt + \sigma(X(t))dW,$$
$$X(0) = x$$
(2)

where $x \in \mathbb{R}^r$, $u(\cdot)$ is a U-valued, measurable process with $U \subset \mathbb{R}^d$ being a compact control set, $W(\cdot)$ is an r-dimensional standard Brownian motion, and τ is the first exit time of the diffusion from a bounded domain D, that is, $\tau = \min\{t : X(t) \notin D^0\}$ with D^0 denoting the interior of D, $b(\cdot, \cdot) : \mathbb{R}^r \times \mathbb{R}^d \mapsto \mathbb{R}^r$, $\sigma(\cdot) : \mathbb{R}^r \mapsto \mathbb{R}^r \times \mathbb{R}^r$, and $R(\cdot, \cdot) : \mathbb{R}^r \times \mathbb{R}^d \mapsto \mathbb{R}$ and $B(\cdot) : \mathbb{R}^r \mapsto \mathbb{R}$. In the above, $b(\cdot)$ is the control-dependent drift, $\sigma(\cdot)$ is the diffusion matrix, $R(\cdot)$ is the running cost, and $B(\cdot)$ is the terminal or boundary cost. Throughout the entry, we assume that the stopping time $\tau < \infty$ with probability one (w.p.1) for simplicity. Denote the value function by $V(x) = \inf_u J(x, u(\cdot))$, where the inf is taken over all admissible controls. Write the transpose of $Y \in \mathbb{R}^{d_1 \times d_2}$ as Y' with $d_1, d_2 \geq 1$, $a(x) = \sigma(x)\sigma'(x)$, and define the generator of the controlled Markov process by

$$\mathcal{L}^u f(x) = \frac{1}{2}\mathrm{tr}(a(x)f_{xx}(x)) + b'(x, u)f_x(x), \tag{3}$$

for a suitably smooth function $f(\cdot)$, where $f_x(\cdot)$ and $f_{xx}(\cdot)$ denote the gradient and Hessian of $f(\cdot)$, respectively. Note that the operator is control dependent. Using ∂D to denote the boundary of D, then the associated Hamilton-Jacobi-Bellman (HJB) equation satisfied by the value function is given by

$$\begin{cases} \inf_u[\mathcal{L}^u V(x) + R(x, u)] = 0, \; x \in D^0, \\ V(x) = B(x), \; x \in \partial D. \end{cases} \tag{4}$$

The subject matter of this article is to solve the optimal stochastic control problem numerically.

The rest of the entry is arranged as follows. Section "Markov Chain Approximation" focuses on Markov chain approximation. It illustrates how one can construct the controlled Markov chain in discrete time for the approximation of the continuous-time stochastic control problems. Section "Illustration: A One-Dimensional Problem" uses a one-dimensional case as an example

for illustration. Section "Numerical Computation" discusses the implementation issues. We conclude the entry with a few further remarks.

Markov Chain Approximation

The main idea was initiated in Kushner (1977) and streamlined, extended, and further developed in Kushner and Dupuis (1992). An earlier paper describing how to discretize the elliptic HJB equation and then interpret it according to a controlled Markov chain can be found in Kushner and Kleinman (1968). This section illustrates the Markov chain approximation methods with simple setup. The reader is suggested to read the references mentioned above for a comprehensive treatment. To begin, let $h > 0$ be a small "step size" in the approximation. Instead of the domain D, we need to work with a finite set to ensure computational feasibility. Set $\mathbb{R}_h^r$ to be r-dimensional lattice cube, i.e., $\mathbb{R}_h^r = \{\dots, -2h, -h, 0, h, 2h, \dots\}^r$ (an r-dimensional product of the indicated set). Denote the interior of D by D^0, and define $D_h^0 = D^0 \cap \mathbb{R}_h^r$. We shall construct a controlled, discrete-time Markov chain, whose transition probabilities have desired properties in line with the controlled diffusion and whose values are in D_0^h. Suppose that $\{\alpha_n^h\}$ is a time-homogeneous, discrete-time, controlled Markov chain with finite state space D_0^h and transition probabilities $P = (p(x, y|v))$ with $x, y \in D_0^h$. Here we only consider the case that the Markov chain has a finite state space. This is sufficient for our computational purposes. At any time n, the control action is a random variable denoted by u_n^h taking values in a compact set U. Set the interpolation interval by $\Delta t^h(x, v) > 0$ and write $\Delta t_n^h = \Delta t^h(\alpha_n, u_n^h)$ such that $\sup_{x,v} \Delta t^h(x, v) \to 0$ as $h \to 0$ but $\inf_{x,v} \Delta t^h(x, v) > 0$ for each $h > 0$. The control is admissible if the Markov property $P(\alpha_{n+1}^h = y|\alpha_i^h, u_i^h; i \leq n) = P(\alpha_{n+1}^h = y|\alpha_n^h, u_n^h) = P(\alpha_n^h, y|u_n^h)$ holds. Use U^h to denote the collection of controls, which

N

are determined by a sequence of measurable functions $F_n^h(\cdot)$ such that $u_n^h = F_n^h(\alpha_k^h, k \leq n; u_k^h, k < n)$. Denote the conditional expectation given $\{\alpha_j^h, u_j^h : j \leq n, \alpha_n^h = x, u_n^h = v\}$ by E_n^h. We say that a control policy is locally consistent if

$$E_n^h \alpha_n^h = b(x, v) \Delta t^h(x, v) + o(\Delta^h(x, v)),$$

$$E_n^h [\Delta \alpha_n^h - E_n^h \Delta \alpha_n^h][\Delta \alpha_n^h - E_n^h \Delta \alpha_n^h]' = a(x) \Delta t^h(x, v) + o(\Delta t^h(x, v)), \tag{5}$$

$$a(x) = \sigma(x)\sigma'(x), \quad |\Delta \alpha_n^h| \to 0 \text{ as } h \to 0 \text{ uniformly in } n, \omega,$$

where $\Delta \alpha_n^h = \alpha_{n+1}^h - \alpha_n^h$. The meaning of the local consistency can be seen from the corresponding controlled diffusion (2) (with $X(0) = x$ and $u(t) = v$ for $t \in [0, \delta]$, where $\delta > 0$ is a small parameter) in that $E_x(X(\delta) - x) = b(x, v)\delta + o(\delta)$, $E_x[X(\delta) - x][X(\delta) - x]' = a(x)\delta + o(\delta)$. Let ν_h be the first time that $\{\alpha_n^h\}$ leaves the set D_h^0. We have an approximation for the cost function of the controlled diffusion (1) given by

$$J^h(x, u^h) = E_x^{u^h} \left[\sum_{j=0}^{\nu_h - 1} R(\alpha_j^h, u_j^h) \Delta t_j^h + B(\alpha_{\nu_h}^h) \right]. \tag{6}$$

Define $t_n^h = \sum_{j=0}^{n-1} \Delta t_j^h$ and the continuous-time interpolations $\alpha^h(t) = \alpha_n^h$, $u_n^h = u_n^h$ for $t \in [t_n^h, t_{n+1}^h)$. Define the first exit time of $\alpha^h(\cdot)$ from D_h^0 by $\tau_h = t_{\nu_h}^h$. Corresponding to the continuous-time problems, the first term on the right-hand side of (6) represents the running cost and the last term gives the terminal cost. Denote the value function by $V^h(x)$. Then it satisfies the dynamic programming equation

$$V^h(x) = \begin{cases} \inf_{v \in U^h} [R(x, v) \Delta t^h(x, v) \\ \qquad + \sum_y p^h(x, y|v) V^h(y)], \ x \in D_h^0, \\ B(x), \ x \notin D_h^0. \end{cases} \tag{7}$$

Proving the convergence of the numerical algorithms is an important task. This requires the use of local consistency, interpolation of the approximating sequences in continuous time, as well as martingale representation. The proof is facilitated by the use of the so-called relaxed controls (Kushner and Dupuis 1992, p. 267), which enables us to characterize the limit under the framework of weak convergence. The detailed argument is beyond the scope of this entry. We refer the reader to Kushner and Dupuis (1992, Chapter 10) for further reading on the proof of convergence and the conditions needed.

Illustration: A One-Dimensional Problem

In this section, we use a one-dimensional example to illustrate the Markov chain approximation methods, which enables us to present the results with a better visualization. Consider (2) with $x \in \mathbb{R}$. We proceed to find the transition probabilities and interpolation intervals for the Markov chain $\{\alpha_n^h\}$. To construct a controlled Markov chain that is locally consistent, we first consider a special case, namely, the control space has only one admissible control $u^h \in U^h$. In this case, min in (7) can be removed. Discretize the HJB equation using upwind finite difference method with step size $h > 0$ by

$$V(x) \to V^h(x)$$

$$V_x(x) \to \frac{V^h(x + h) - V^h(x)}{h} \text{ for } b(x, v) > 0,$$

$$V_x(x) \to \frac{V^h(x) - V^h(x - h)}{h} \text{ for } b(x, v) < 0,$$

$$V_{xx}(x) \to \frac{V^h(x + h) - 2V^h(x) + V^h(x - h)}{h^2}.$$

For $x \in D_h^0$, it leads to

$$\frac{V^h(x+h) - V^h(x)}{h} b^+(x, v) - \frac{V^h(x) - V^h(x-h)}{h} b^-(x, v)$$
$$+ \frac{a(x)}{2} \frac{V^h(x+h) - 2V^h(x) + V^h(x-h)}{h^2} + R(x, v) = 0,$$

where b^+ and b^- are the positive and negative parts of b, respectively. Comparing with the dynamic programming equation, we obtain the transition probabilities

$$p^h(x, x+h)|v) = \frac{(a(x)/2) + hb^+(x, v)}{\tilde{\Delta}},$$
$$p^h(x, x-h)|v) = \frac{(a(x)/2) + hb^-(x, v)}{\tilde{\Delta}},$$
$$p^h(\cdot) = 0, \quad \text{otherwise}, \quad \Delta t^h(x, v) = \frac{h^2}{\tilde{\Delta}},$$

with $\tilde{\Delta} = a(x) + h|b(x, v)|$ being well defined. With the transition probabilities given above, we can proceed to verify the local consistency by straight forward calculations and prove the desired convergence.

Numerical Computation

To numerically approximate the controlled diffusions, frequently used methods are either value iterations or policy iterations (iteration in policy space). Using Markov chain approximation in conjunction with either value iteration or iteration in policy space, we can further obtain a sequence of value functions $\{V^{h,n}\}$ such that $V^{h,n} \to V^h$ as $n \to \infty$. The procedures can be described as follows.

Value Iteration
1. Given a tolerance $\varepsilon > 0$, set $n = 0$; for $x \in D_h^0$, set $V^{h,0} = $ constant (for instance, 0).
2. Using $V^{h,n}$ obtained in (7) to obtain $V^{h,n+1}$.
3. If $|V^{h,n+1} - V^{h,n}| > \varepsilon$, go to Step 3 above with $n \to n + 1$.

Policy Iteration
1. Given a tolerance $\varepsilon > 0$, set $n = 0$; for $x \in D_h^0$, take an initial control $u_0^h(x) = $ constant. Use $u_0^h(x)$ in lieu of v, solve (7) to find $V^{h,0}(\cdot)$.

2. Find an improved control by
$u^{h,n+1}(x) := \text{argmin}_{v \in U^h}[\sum_y p^h((x, y)|v) V^{h,n}(y) + R(x, v)\Delta t^h(x, v)].$
3. Find $V^{h,n+1}(\cdot)$ with $u^{h,n+1}(\cdot)$ by solving (7). If $|V^{h,n+1} - V^{h,n}| > \varepsilon$, go to Step 2 above with $n \to n + 1$.

Further Remarks

Variations of the Problems. Variants of the problems can be considered. For example, one may consider nonlinear filtering problems or singularly perturbed control and filtering problems. For problems arising in manufacturing systems, one often needs to treat controlled Markov chain with no diffusion terms. Such a case can also be handled by the Markov chain approximation methods; see Sethi and Zhang (1994) for the problem and Yin and Zhang (2013, Chapter 9) for the numerical methods. In this article, we mainly discussed the approach by using probabilistic approach for getting the weak convergence of the interpolations of the controlled Markov chain. One can also use the so-called viscosity solution methods to treat the convergence; see Barles and Souganidis (1991) (also Kushner and Dupuis 1992, Chapter 11).

Variance Control. In this entry, only drift involves control term. When the diffusion term is also subject to controls, the problem becomes more difficult. In Peng (1990), the idea of using backward stochastic differential equations was initiated, which had significant impact in the development of such stochastic control problems. Detailed discussions can be found in Yong and Zhou (1999). The numerical problems for diffusion term involving controls can also be treated; see Kushner (2000) for further discussion. In this case, the so-called numerical noise or numerical viscosity can be introduced, so care must be taken.

N

Complex Models Involving Jump and Switching. Note that only controlled diffusions are considered in this entry. More complex models such as controlled jump diffusions (Kushner and Dupuis 1992), switching diffusions (Yin and Zhu 2010), and switching jump diffusions can be treated (Song et al. 2006). Differential games can also be treated (Kushner 2002; Song et al. 2008).

Differential Delay Systems. Stochastic differential delay systems may come into play. The corresponding numerical algorithms have been studied extensively in Kushner (2008). Due to their inherent infinite dimensionality, a main issue here concerns suitable finite approximation to the memory segments.

Rates of Convergence. This entry mainly discusses the convergence of the approximation methods. There is also much interest in ascertaining rates of convergence. Such effort goes back to the paper Menaldi (1989) (see also Zhang 2006). Subsequently, it has been resurgent effort in dealing with this issue from a nonlinear partial differential equation point of view; see Krylov (2000). Our recent work Song and Yin (2009) complements the study by providing a probabilistic approach for treating switching diffusions.

Stochastic Approximation. In certain optimal control problems, the optimal controls or near-optimal controls turn out to be of threshold type. An alternative way of solving such problems leading to at least suboptimal or near-optimal control is to use a stochastic approximation approach; see Kushner and Yin (2003) for a comprehensive treatment of stochastic approximation algorithms. Some successful examples include manufacturing systems (Yin and Zhang 2013, Section 9.3) and liquidation decision making (Yin et al. 2002).

Numerical Methods for Nonlinear Optimal Control Problems

Lars Grüne
Mathematical Institute, University of Bayreuth, Bayreuth, Germany

Abstract

In this article we describe the three most common approaches for numerically solving nonlinear optimal control problems governed by ordinary differential equations. For computing approximations to optimal value functions and optimal feedback laws, we present the Hamilton-Jacobi-Bellman approach. For computing approximately optimal open-loop control functions and trajectories for a single initial value, we outline the indirect approach based on Pontryagin's maximum principle and the approach via direct discretization.

Keywords

Direct discretization; Hamilton-Jacobi-Bellman equations; Optimal control; Ordinary differential equations; Pontryagin's maximum principle

Introduction

This article concerns optimal control problems governed by nonlinear ordinary differential equations of the form

$$\dot{x}(t) = f(x(t), u(t)) \tag{1}$$

with $f : \mathbb{R} \times \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R}^n$. We assume that for each initial value $x \in \mathbb{R}^n$ and measurable control function $u(\cdot) \in L^\infty(\mathbb{R}, \mathbb{R}^m)$ there exists a unique solution $x(t) = x(t, x, u(\cdot))$ of (1) satisfying $x(0, x, u(\cdot)) = x$.

Given a state constraint set $X \subseteq \mathbb{R}^n$ and a control constraint set $U \subseteq \mathbb{R}^m$, a running cost $g : X \times U \to \mathbb{R}$, a terminal cost $F : X \to U$, and

a discount rate $\delta \geq 0$, we consider the optimal control problem

$$\underset{u(\cdot) \in \mathcal{U}^T(x)}{\text{minimize}} \ J^T(x, u(\cdot)) \qquad (2)$$

where

$$J^T(x, u(\cdot)) := \int_0^T e^{-\delta s} g(x(s, x, u(\cdot)), u(s)) ds$$
$$+ \ e^{-\delta T} F(x(T, x, u(\cdot))) \qquad (3)$$

and

$$\mathcal{U}^T(x) :=$$
$$\left\{ u(\cdot) \in L^\infty(\mathbb{R}, U) \ \middle| \ \begin{matrix} x(s, x, u(\cdot)) \in X \\ \text{for all } s \in [0, T] \end{matrix} \right\} \qquad (4)$$

In addition to this finite horizon optimal control problem, we also consider the infinite horizon problem in which T is replaced by "∞," i.e.,

$$\underset{u(\cdot) \in \mathcal{U}^\infty(x)}{\text{minimize}} \ J^\infty(x, u(\cdot)) \qquad (5)$$

where

$$J^\infty(x, u(\cdot)) := \int_0^\infty e^{-\delta s} g(x(s, x, u(\cdot)), u(s)) ds \qquad (6)$$

and

$$\mathcal{U}^\infty(x) :=$$
$$\left\{ u(\cdot) \in L^\infty(\mathbb{R}, U) \ \middle| \ \begin{matrix} x(s, x, u(\cdot)) \in X \\ \text{for all } s \geq 0 \end{matrix} \right\}, \qquad (7)$$

respectively.

The term "solving" (2)–(4) or (5)–(7) can have various meanings. First, the optimal value functions

$$V^T(x) = \inf_{u(\cdot) \in \mathcal{U}^T(x)} J^T(x, u(\cdot))$$

or

$$V^\infty(x) = \inf_{u(\cdot) \in \mathcal{U}^\infty(x)} J^\infty(x, u(\cdot))$$

may be of interest. Second, and often more importantly, one would like to know the optimal

control policy. This can be expressed in *open-loop* form $u^\star : \mathbb{R} \to U$, in which the function $u^\star$ depends on the initial value x and on the initial time which we set to 0 here. Alternatively, the optimal control can be computed in state- and time-dependent *closed-loop* form, in which a feedback law $\mu^\star : \mathbb{R} \times X \to U$ is sought. Via $u^\star(t) = \mu^\star(t, x(t))$, this feedback law can then be used in order to generate the time-dependent optimal control function for all possible initial values. Since the feedback law is evaluated along the trajectory, it is able to react to perturbations and uncertainties which may make $x(t)$ deviate from the predicted path. Finally, knowing $u^\star$ or $\mu^\star$, one can reconstruct the corresponding optimal trajectory by solving

$$\dot{x}(t) = f(x(t), u^\star(t)) \quad \text{or}$$
$$\dot{x}(t) = f(x(t), \mu^\star(t, x(t))).$$

Hamilton-Jacobi-Bellman Approach

In this section we describe the numerical approach to solving optimal control problems via Hamilton-Jacobi-Bellman equations. We first describe how this approach can be used in order to compute approximations to the optimal value function V^T and V^∞, respectively, and afterwards how the optimal control can be synthesized using these approximations. In order to formulate this approach for finite horizon T, we interpret $V^T(x)$ as a function in T and x. We denote differentiation w.r.t. T and x with subscript T and x, i.e., $V_x^T(x) = dV^T(x)/dx$, $V_T^T(x) = dV^T(x)/dT$ etc.

We define the Hamiltonian of the optimal control problem as

$$H(x, p) := \max_{u \in U} \{ -g(x, u) - p \cdot f(x, u) \},$$

with $x, p \in \mathbb{R}^n$, f from (1), g from (3) or (6), and "$\cdot$" denoting the inner product in $\mathbb{R}^n$. Then, under appropriate regularity conditions on the problem data, the optimal value functions V^T and V^∞ satisfy the first order partial differential equations (PDEs)

$$V_T^T(x) + \delta V^T(x) + H(x, V_x^T(x)) = 0$$

and

$$\delta V^\infty(x) + H(x, V_x^\infty(x)) = 0$$

in the viscosity solution sense. In the case of V^T, the equation holds for all $T \geq 0$ with the boundary condition $V^0(x) = F(x)$.

The framework of viscosity solutions is needed because in general the optimal value functions will not be smooth; thus, a generalized solution concept for PDEs must be employed (see Bardi and Capuzzo Dolcetta 1997). Of course, appropriate boundary conditions are needed at the boundary of the state constraint set X.

Once the Hamilton-Jacobi-Bellman characterization is established, one can compute numerical approximations to V^T or V^∞ by solving these PDEs numerically. To this end, various numerical schemes have been suggested, including various types of finite element and finite difference schemes. Among those, semi-Lagrangian schemes Falcone (1997) or Falcone and Ferretti (2013) allow for a particularly elegant interpretation in terms of optimal control synthesis, which we explain for the infinite horizon case.

In the semi-Lagrangian approach, one takes advantage of the fact that by the chain rule for $p = V_x^\infty(x)$ and constant control functions u, the identity

$$\delta V^\infty(x) - p \cdot f(x, u) = \frac{d}{dt}\Big|_{t=0} - (1 - \delta t) V^\infty$$
$$(x(t, x, u))$$

holds. Hence, the left-hand side of this equality can be approximated by the difference quotient

$$\frac{V^\infty(x) - (1 - \delta h) V^\infty(x(h, x, u))}{h}$$

for small $h > 0$. Inserting this approximation into the Hamilton-Jacobi-Bellman equation, replacing $x(h, x, u)$ by a numerical approximation $\tilde{x}(h, x, u)$ (in the simplest case, the Euler method $\tilde{x}(h, x, u) = x + hf(x, u)$), multiplying

by h, and rearranging terms, one arrives at the equation

$$V_h^\infty(x) = \min_{u \in U}\{hg(x, u)$$
$$+ (1 - \delta h) V_h^\infty(\tilde{x}(h, x, u))\}$$

defining an approximation $V_h^\infty \approx V^\infty$. This is now a purely algebraic dynamic programming-type equation which can be solved numerically, e.g., by using a finite element approach. The equation is typically solved iteratively using a suitable minimization routine for computing the "min" in each iteration (in the simplest case, U is discretized with finitely many values and the minimum is determined by direct comparison). We denote the resulting approximation of V^∞ by $\tilde{V}_h^\infty$. Here, approximation is usually understood in the L^∞ sense (see Falcone 1997 or Falcone and Ferretti 2013).

The semi-Lagrangian scheme is appealing for synthesis of an approximately optimal feedback because V_h^∞ is the optimal value function of the auxiliary discrete-time problem defined by $\tilde{x}$. This implies that the expression

$$\mu_h^\star(x) := \operatorname*{argmin}_{u \in U}\{hg(x, u)$$
$$+ (1 - \delta h) V_h^\infty(\tilde{x}(h, x, u))\},$$

is an optimal feedback control value for this discrete-time problem for the next time step, i.e., on the time interval $[t, t + h]$ if $x = x(t)$. This feedback law will be approximately optimal for the continuous-time control system when applied as a discrete-time feedback law, and this approximate optimality remains true if we replace V_h^∞ in the definition of $\mu_h^\star$ by its numerically computable approximation $\tilde{V}_h^\infty$. A similar construction can be made based on any other numerical approximation $\tilde{V}^\infty \approx V^\infty$, but the explicit correspondence of the semi-Lagrangian scheme to a discrete-time auxiliary system facilitates the interpretation and error analysis of the resulting control law.

The main advantage of the Hamilton-Jacobi approach is that it directly computes an approximately optimal feedback law. Its main

disadvantage is that the number of grid nodes needed for maintaining a given accuracy in a finite element approach to compute $\tilde{V}_h^\infty$ in general grows exponentially with the state dimension n. This fact – known as the *curse of dimensionality* – restricts this method to low-dimensional state spaces. Unless special structure is available which can be exploited, as, e.g., in the max-plus approach (see McEneaney 2006), it is currently almost impossible to go beyond state dimensions of about $n = 10$, typically less for strongly nonlinear problems.

Maximum Principle Approach

In contrast to the Hamilton-Jacobi-Bellman approach, the approach via Pontryagin's maximum principle does not compute a feedback law. Instead, it yields an approximately open-loop optimal control $u^\star$ together with an approximation to the optimal trajectory $x^\star$ for a fixed initial value. We explain the approach for the finite horizon problem. For simplicity of presentation, we omit state constraints in our presentation, i.e., we set $X = \mathbb{R}^n$ and refer to, e.g., Vinter (2000), Bryson and Ho (1975), or Grass et al. (2008) for more general formulations as well as for rigorous versions of the following statements.

In order to state the maximum principle (which, since we are considering a minimization problem here, could also be called minimum principle), we define the non-minimized Hamiltonian as

$$\mathcal{H}(x, p, u) = g(x, u) + p \cdot f(x, u).$$

Then, under appropriate regularity assumptions, there exists an absolutely continuous function $p : [0, T] \to \mathbb{R}^n$ such that the optimal trajectory $x^\star$ and the corresponding optimal control function $u^\star$ for (2)–(4) satisfy

$$\dot{p}(t) = \delta p(t) - \mathcal{H}_x(x^\star(t), p(t), u^\star(t)) \quad (8)$$

with terminal or transversality condition

$$p(T) = F_x(x^\star(T)) \quad (9)$$

and

$$u^\star(t) = \underset{u \in U}{\mathrm{argmin}}\, \mathcal{H}(x^\star(t), p(t), u), \quad (10)$$

for almost all $t \in [0, T]$ (see Grass et al. 2008, Theorem 3.4). The variable p is referred to as the *adjoint* or *costate* variable.

For a given initial value $x_0 \in \mathbb{R}^n$, the numerical approach now consists of finding functions $x : [0, T] \to \mathbb{R}^n$, $u : [0, T] \to U$ and $p : [0, T] \to \mathbb{R}^n$ satisfying

$$\dot{x}(t) = f(x(t), u(t)) \quad (11)$$

$$\dot{p}(t) = \delta p(t) - \mathcal{H}_x(x(t), p(t), u(t)) \quad (12)$$

$$u(t) = \underset{u \in U}{\mathrm{argmin}}\, \mathcal{H}(x(t), p(t), u) \quad (13)$$

$$x(0) = x_0, \quad p(T) = F_x(x(T)) \quad (14)$$

for $t \in [0, T]$. Depending on the regularity of the underlying data, the conditions (11)–(14) may only be necessary but not sufficient for x and u being an optimal trajectory $x^\star$ and control function $u^\star$, respectively. However usually x and u satisfying these conditions, are good candidates for the optimal trajectory and control, thus justifying the use of these conditions for the numerical approach. If needed, optimality of the candidates can be checked using suitable sufficient optimality conditions for which we refer to, e.g., Maurer (1981) or Malanowski et al. (2004). Due to the fact that in the maximum principle approach first optimality conditions are derived which are then discretized for numerical simulation, it is also termed *first optimize then discretize*.

Solving (11)–(14) numerically amounts to solving a boundary value problem, because the condition $x^\star(0) = x_0$ is posed at the beginning of the time interval $[0, T]$ while the condition $p(T) = F_x(x^\star(T))$ is required at the end. In order to solve such a problem, the simplest approach is the *single shooting* method which proceeds as follows:

We select a numerical scheme for solving the ordinary differential equations (11) and (12) for $t \in [0, T]$ with initial conditions $x(0) = x_0$,

$p(0) = p_0$ and control function $u(t)$. Then, we proceed iteratively as follows:

(0) Find initial guesses $p_0^0 \in \mathbb{R}^n$ and $u^0(t)$ for the initial costate and the control, fix $\varepsilon > 0$, and set $k := 0$.

(1) Solve (11) and (12) numerically with initial values x_0 and p_0^k and control function u^k. Denote the resulting trajectories by $\tilde{x}^k(t)$ and $\tilde{p}^k(t)$.

(2) Apply one step of an iterative method for solving the zero-finding problem $G(p) = 0$ with

$$G(p_0^k) := \tilde{p}^k(T) - F_x(\tilde{x}^k(T))$$

for computing p_0^{k+1}. For instance, in case of the Newton method we get

$$p_0^{k+1} := p_0^k - DG(p_0^k)^{-1} G(p_0^k).$$

If $\|p_0^{k+1} - p_0^k\| < \varepsilon$, stop; else compute

$$u^{k+1}(t) := \underset{u \in U}{\operatorname{argmin}} \mathcal{H}(x^k(t), p^k(t), u),$$

set $k := k + 1$, and go to (1).

The procedure described in this algorithm is called *single shooting* because the iteration is performed on the single initial value p_0^k. For an implementable scheme, several details still need to be made precise, e.g., how to parameterize the function $u(t)$ (e.g., piecewise constant, piecewise linear or polynomial), how to compute the derivative DG and its inverse (or an approximation thereof), and the argmin in (2). The last task considerably simplifies if the structure of the optimal control, e.g., the number of switchings in case of a bang-bang control, is known.

However, even if all these points are settled, the set of initial guesses p_0^0 and u^0 for which the method is going to converge to a solution of (11)–(14) tends to be very small. One reason for this is that the solutions of (11) and (12) typically depend very sensitively on p_0^0 and u^0. In order to circumvent this problem, *multiple shooting* can be used. To this end, one selects a time grid $0 = t_0 < t_1 < t_2 <$

$\ldots < t_N = T$ and in addition to p_0^k introduces variables $x_1^k, \ldots, x_{N-1}^k, p_1^k, \ldots, p_{N-1}^k \in \mathbb{R}^n$. Then, starting from initial guesses p_0^0, u^0, and $x_1^0, \ldots, x_{N-1}^0, p_1^0, \ldots, p_{N-1}^0$, in each iteration the Eqs. (11)–(14) are solved numerically on the intervals $[t_j, t_{j+1}]$ with initial values x_j^k and p_j^k, respectively. We denote the respective solutions in the k-th iteration by $\tilde{x}_j^k$ and $\tilde{p}_j^k$. In order to enforce that the trajectory pieces computed on the individual intervals $[t_j, t_{j+1}]$ fit together continuously, the map G is redefined as

$$G(x_1^k, \ldots, x_{N-1}^k, p_0^k, p_1^k, \ldots, p_{N-1}^k) =$$

$$\begin{pmatrix} \tilde{x}_0^k(t_1) - x_1^k \\ \vdots \\ \tilde{x}_{N-2}^k(t_1) - x_{N-1}^k \\ \tilde{p}_0^k(t_1) - p_1^k \\ \vdots \\ \tilde{p}_{N-2}^k(t_1) - p_{N-1}^k \\ \tilde{p}_{N-1}^k(T) - F_x(\tilde{x}_{N-1}^k(T)) \end{pmatrix}.$$

The benefit of this approach is that the solutions on the shortened time intervals depend much less sensitively on the initial values and the control, thus making the problem numerically much better conditioned. The obvious disadvantage is that the problem becomes larger as the function G is now defined on a much higher dimensional space but this additional effort usually pays off.

While the convergence behavior for the multiple shooting method is considerably better than for single shooting, it is still a difficult task to select good initial guesses x_j^0, p_j^0 and u^0. In order to accomplish this, homotopy methods can be used (see, e.g., Pesch 1994) or the result of a direct approach as presented in the next section can be used as an initial guess. The latter can be reasonable as the maximum principle-based approach can yield approximations of higher accuracy than the direct method.

In the presence of state constraints or mixed state and control constraints, the conditions (12)–(14) become considerably more technical and thus more difficult to be implemented numerically (cf. Pesch 1994).

Direct Discretization

Despite being the most straightforward and simple of the approaches described in this article, the direct discretization approach is currently the most widely used approach for computing single finite horizon optimal trajectories. In the direct approach, we first discretize the problem and then solve a finite dimensional nonlinear optimization problem (NLP), i.e., we *first discretize, then optimize*. The main reasons for the popularity of this approach are the simplicity with which constraints can be handled and the numerical efficiency due to the availability of fast and reliable NLP solvers.

The direct approach again applies to the finite horizon problem and computes an approximation to a single optimal trajectory $x^\star(t)$ and control function $u^\star(t)$ for a given initial value $x_0 \in X$. To this end, a time grid $0 = t_0 < t_1 < t_2 < \ldots < t_N = T$ and a set $\mathcal{U}_d$ of control functions which are parameterized by finitely many values are selected. The simplest way to do so is to choose $u(t) \equiv u_j \in U$ for all $t \in [t_i, t_{i+1}]$. However, other approaches like piecewise linear or piecewise polynomial control functions are possible, too. We use a numerical algorithm for ordinary differential equations in order to approximately solve the initial value problems

$$\dot{x}(t) = f(x(t), u_i), \quad x(t_i) = x_i \qquad (15)$$

for $i = 0, \ldots, N - 1$ on $[t_i, t_{i+1}]$. We denote the exact and numerical solution of (15) by $x(t, t_i, x_i, u_i)$ and $\tilde{x}(t, t_i, x_i, u_i)$, respectively. Finally, we choose a numerical integration rule in order to compute an approximation

$$I(t_i, t_{i+1}, x_i, u_i) \approx \int_{t_i}^{t_{i+1}} e^{-\delta t}$$
$$g(x(t, t_i, x_i, u), u(t)) dt.$$

In the simplest case, one might choose $\tilde{x}$ as the Euler scheme and I as the rectangle rule, leading to

$$\tilde{x}(t_{i+1}, t_i, x_i, u_i) = x_i + (t_{i+1} - t_i) f(x_i, u_i)$$

and

$$I(t_i, t_{i+1}, x_i, u_i) = (t_{i+1} - t_i) e^{-\delta t_i} g(x_i, u_i).$$

Introducing the optimization variables $u_0, \ldots, u_{N-1} \in \mathbb{R}^m$ and $x_1, \ldots, x_N \in \mathbb{R}^n$, the discretized version of (2)–(4) reads

$$\underset{x_j \in \mathbb{R}^n, u_j \in \mathbb{R}^m}{\text{minimize}} \sum_{i=0}^{N-1} I(t_i, t_{i+1}, x_i, u) + e^{-\delta T} F(x_N)$$

subject to the constraints

$$
\begin{aligned}
u_j &\in U, & j &= 0, \ldots, N-1 \\
x_j &\in X, & j &= 1, \ldots, N \\
x_{j+1} &= \tilde{x}(t_{j+1}, t_j, x_j, u), & j &= 0, \ldots, N
\end{aligned}
$$

This way, we have converted the optimal control problem (2)–(4) into a finite dimensional nonlinear optimization problem (NLP). As such, it can be solved with any numerical method for solving such problems. Popular methods are, for instance, sequential quadratic programming (SQP) or interior point (IP) algorithms. The convergence of this approach was proved in Malanowski et al. (1998); for an up-to-date account on theory and practice of the method, see Gerdts (2012) and Betts (2010). These references also explain how information about the costates $p(t)$ can be extracted from a direct discretization, thus linking the approach to the maximum principle.

The direct method sketched here is again a multiple shooting method, and the benefit of this approach is the same as for solving boundary problems, thanks to the short intervals $[t_i, t_{i+1}]$; the solutions depend much less sensitively on the data than the solution on the whole interval $[0, T]$, thus making the iterative solution of the resulting discretized NLP much easier. The price to pay is again the increase of the number of optimization variables. However, due to the particular structure of the constraints guaranteeing continuity of the solution, the resulting matrices in the NLP have a particular structure which can be exploited numerically by a method called *condensing* (see Bock and Plitt 1984).

An alternative to multiple shooting methods are collocation methods, in which the internal variables of the numerical algorithm for solving (15) are also optimization variables. However, nowadays, the multiple shooting approach as described above is usually preferred. For a more detailed description of various direct approaches, see also Binder et al. (2001), Sect. 5.

Further Approaches for Infinite Horizon Problems

The last two approaches only apply to finite horizon problems. While the maximum principle approach can be generalized to infinite horizon problems, the necessary conditions become weaker and the numerical solution becomes considerably more involved (see Grass et al. 2008). Both the maximum principle and the direct approach can, however, be applied in a receding horizon fashion, in which an infinite horizon problem is approximated by the iterative solution of finite horizon problems. The resulting control technique is known under the name of model predictive control (MPC; see Grüne and Pannek 2011), and under suitable assumptions, a rigorous approximation result can be established.

Summary and Future Directions

The three main numerical approaches to optimal control are:

- The Hamilton-Jacobi-Bellman approach, which provides a global solution in feedback form but is computationally expensive for higher dimensional systems
- The Pontryagin maximum principle approach which computes single optimal trajectories with high accuracy but needs good initial guesses for the iteration
- The direct approach which also computes single optimal trajectories but is less demanding in terms of the initial guesses at the expense of a somewhat lower accuracy

Currently, the main trends in numerical optimal control lie in the areas of Hamilton-Jacobi-

Bellman equations and direct discretization. For the former, the development of discretization schemes suitable for increasingly higher dimensional problems is in the focus. For the latter, the popularity of these methods in online applications like MPC triggers continuing effort to make this approach faster and more reliable.

Beyond ordinary differential equations, the development of numerical algorithms for the optimal control of partial differential equations (PDEs) has attracted considerable attention during the last years. While many of these methods are still restricted to linear systems, in the near future we can expect to see many extensions to (classes of) nonlinear PDEs. It is worth noting that for PDEs, maximum principle-like approaches are more popular than for ordinary differential equations.

Abstract

An observer-based controller is a dynamic
feedback controller with a two-stage structure.
First, the controller generates an estimate of the
state variable of the system to be controlled,
using the measured output and known input
of the system. This estimate is generated by a
state observer for the system. Next, the state
estimate is treated as if it were equal to the exact
state of the system, and it is used by a static
state feedback controller. Dynamic feedback
controllers with this two-stage structure appear
in various control synthesis problems for linear
systems. In this entry, we explain observer-based
control in the context of internal stabilization by
dynamic measurement feedback.

Detectability; Dynamic output feedback control;
Internal stabilization; Separation principle;
Stabilizability; State observers; Static state
feedback

Introduction

In this entry, we explain the notion of observer-
based feedback control. Given a to-be-controlled
system in input-state-output form, together with
a control objective, the problem is to design a
feedback controller such that the closed-loop
system meets the objective. In the case when
all state variables of the system are available
for control, the design problem is considered
to be simpler, and often the controller can be
chosen to be a static state feedback control law.
In the more general case where the controller
has access only to a linear function of the
state variables, the problem is more involved
and requires the design of a dynamic feedback
control law. The key idea of observer-based
feedback control is the following. As a first
step, one determines a state observer for the
system, i.e., a system that estimates the state of
the system based on the measured outputs and
inputs of the system. Next, the state estimate
is treated as if it were exactly equal to the
actual state of the system and is used by a
static state feedback controller. In this way, a
dynamic feedback controller is obtained that is
composed of a (dynamic) state observer and a
static feedback part.

Dynamic Output Feedback Control

Consider the controlled and observed system Σ:

$$\begin{aligned}
\dot{x}(t) &= Ax(t) + Bu(t) + Ed(t), \\
y(t) &= Cx(t), \\
z(t) &= Hx(t),
\end{aligned} \tag{1}$$

with $x(t) \in \mathcal{X} = \mathbb{R}^n$ the state, $u(t) \in \mathbb{R}^m$ the control input, and $y(t) \in \mathbb{R}^p$ the measured output. The signal $d(t)$ may represent a disturbance input or a desired reference signal, while the signal $z(t)$ is a controlled output signal. A, B, C, E, and H are maps (or matrices). In general, a linear controller for this system is a finite-dimensional linear time-invariant system Γ represented by

$$\begin{aligned}
\dot{w}(t) &= Kw(t) + Ly(t), \\
u(t) &= Mw(t) + Ny(t).
\end{aligned} \tag{2}$$

The state space of the controller is assumed to be $\mathcal{W} = \mathbb{R}^q$ for some positive integer q. K, L, M, and N are assumed to be linear maps (or matrices). The controller (2) takes the observations y as its input and generates the control function u as its output. The closed-loop system resulting from the interconnection of Σ and Γ is described by the equations

$$\begin{aligned}
\begin{pmatrix} \dot{x}(t) \\ \dot{w}(t) \end{pmatrix} &= \begin{pmatrix} A+BNC & BM \\ LC & K \end{pmatrix} \begin{pmatrix} x(t) \\ w(t) \end{pmatrix} + \begin{pmatrix} E \\ 0 \end{pmatrix} d(t), \\
z(t) &= \begin{pmatrix} H & 0 \end{pmatrix} \begin{pmatrix} x(t) \\ z(t) \end{pmatrix}.
\end{aligned} \tag{3}$$

The control action of interconnecting the controller Γ with the system (1) is called *dynamic feedback*. The state space of the closed-loop system (3) is called the *extended state space* and is equal to the Cartesian product $\mathcal{X} \times \mathcal{W} = \mathbb{R}^{n+q}$. In general, a feedback control problem amounts to finding linear maps K, L, M, and N such that the closed-loop system (3) satisfies the control design specifications.

Observer-Based Controllers

Given the system (1) and a control objective, the problem thus arises on how to determine the maps K, L, M, and N so that the closed-loop systems meet the objective. As an example, take the special case when E in (1) is equal to zero (i.e., the system has no external disturbances or reference signals) and that we wish the closed-loop system (3) to be internally stable, i.e., we want to find the maps K, L, M, and N so that the eigenvalues λ_i of the system map of (3) are in the open left half-plane, i.e., satisfy $\text{Re}(\lambda_i) < 0$ for all i. If we had access to the entire state variable x (instead of only to the linear function $y = Cx$), then this problem would be simpler: assuming that the system is stabilizable (The system $\dot{x} = Ax + Bu$ is called stabilizable if there exists a map F such that $A + BF$ has all its eigenvalues in the open left half-plane), find a map F such that the eigenvalues of $A + BF$ are in the open left half-plane; then take the static state feedback controller $u = Fx$ as the control law. That is, we would choose the state space dimension of the controller Γ equal to 0 and the maps K, L, and M to be void, and we would take $N = F$.

In general, however, we only have access to a given linear function $y = Cx$ of x, determined by the output map C. The key idea of observer-based control is the following:

Use the theory of observer design to find an observer for the state x of the system (1), i.e., an observer that generates an estimate ξ of the system state x based on the measured output y and the control input u. Next, apply a static feedback $u = F\xi$ mimicking the (not permissible) control law $u = Fx$.

This idea leads to a dynamic feedback controller (2) of a very particular structure: the controller is the combination of a state observer (with a certain state space dimension) and a static control law acting on the state estimate. This *two-stage* structure, separating estimation and control, is often called the *separation principle*. We will work out this idea in more detail for the case when $E = 0$ (no external disturbances or reference signals) and the aim is to obtain internal

stability of the system. Before doing this, we first explain the most important material on observers that is needed in the sequel.

State Observers

If the state is not available for measurement, one can try to reconstruct it using a system, called observer, that takes the control input and the measured output of the original system as inputs and yields an output that is an estimate of the state of the original system. Again in case that in the system (1) we have $E = 0$, i.e., there are no disturbance signals. This is illustrated in the following picture:
The quantity ξ is supposed to be an estimate, in some sense, of the state, and w is the state variable of the observer. In general, the observer, denoted by Ω, has equations of the form

$$\begin{aligned} \dot{w}(t) &= Pw(t) + Qu(t) + Ry(t), \\ \xi(t) &= Sw(t). \end{aligned} \quad (4)$$

It turns out that particular choices for P, Q, R, and S, specifically $P = A - GC$ (where the map G has to be determined), $Q = B$, $R = G$, and $S = I$, lead to

$$\dot{\xi}(t) = (A - GC)\xi(t) + Bu(t) + Gy(t). \quad (5)$$

Introducing the *estimation error* $e := \xi - x$ and interconnecting the system (1) with (5), we find that the error e satisfies the differential equation

$$\dot{e}(t) = (A - GC)e(t). \quad (6)$$

Hence all possible errors converge to 0 as t tends to infinity if and only if $A - GC$ is a stability matrix, i.e., has all its eigenvalues in the open left half-plane. In that case, we call (5) a *stable state observer*. Thus, a stable state observer exists if and only if G can be found such that $A - GC$ is a stability matrix. The problem of finding such a G is dual to the problem of finding a matrix F to a pair (A, B) such that $A + BF$ is a stability matrix.

Definition 1 The pair (C, A) is called *detectable* if there exists a matrix G such that $A - GC$ is a stability matrix, i.e., has all its eigenvalues in the open left half-plane.

Theorem 1 *Given system Σ, the following statements are equivalent*:
1. *Σ has a stable state observer.*
2. *(C, A) is detectable.*

The equation for ξ can be rewritten using an artificial output $\eta = C\xi$ as $\dot{\xi} = A\xi + Bu + G(y - \eta)$. The interpretation of this is as follows. If ξ is the exact state, then $\eta = y$, and hence ξ obeys exactly the same differential equation as x. Otherwise, the equation for ξ has to be corrected by a term determined by the *output error $y - \eta$*. Consequently, the state observer consists of an exact replica Σ_{dup} of the original system with an extra input channel for incorporating the output error and an extra output, the state of the observer, which serves as the desired estimate for the state of the original system. The following diagram depicts the situation:
Observer-Based Stabilization

We now work out the ideas put forward in the previous sections for the special case of stabilization by dynamic measurement feedback, i.e., to find a controller (2) such that the closed-loop system (3) is internally stable; equivalently, the system mapping of (3) is a stability matrix. Again, we restrict ourselves to the case when $E = 0$.

We assume that we know how to stabilize by state feedback and how to build a state observer. If we have a plant of which we do not have the state available for measurement, we use a state observer to obtain an estimate of the state, and we apply the state feedback to this estimate rather than to the true state. This is illustrated by the following picture:
Again, consider the system Σ given by (1) and let the observer Ω be given by (5) . Combining this with $u = F\xi$ yields

$$
\begin{aligned}
\dot{x}(t) &= Ax(t) + BF\xi, \\
\dot{\xi}(t) &= (A - GC + BF)\xi(t) + GCx(t).
\end{aligned}
\tag{7}
$$

Introducing again $e := \xi - x$, we obtain, in accordance with the previous section,

$$
\begin{aligned}
\dot{x}(t) &= (A + BF)x(t) + BFe(t), \\
\dot{e}(t) &= (A - GC)e(t).
\end{aligned}
$$

That is, the equation $\dot{x}_e = A_e x_e$ with

$$
x_e := \begin{pmatrix} x \\ e \end{pmatrix}, \quad A_e := \begin{pmatrix} A + BF & BF \\ 0 & A - GC \end{pmatrix}.
$$

Assume that Σ is stabilizable and detectable. Then F and G can be found such that $A + BF$ and $A - GC$ are stability matrices. Since the set of eigenvalues of A_e is the union of those of $A + BF$ and $A - GC$, it follows that A_e is a stability matrix. Consequently, the system $\dot{x}_e = A_e x_e$ is asymptotically stable; equivalently, every solution $x_e = (x, e)$ converges to 0 as t tends to infinity. Of course, if (x, ξ) is a solution of (7), then $\xi = x + e$, with $x_e = (x, e)$ a solution of $\dot{x}_e = A_e x_e$. Hence (x, ξ) also converges to 0 as t goes to infinity. Thus we have proved the "if" part of the following theorem:

Theorem 2 *There exists an internally stabilizing dynamic feedback controller for Σ if and only if Σ is stabilizable and detectable. A controller is given by*

$$
\begin{aligned}
\dot{\xi}(t) &= (A - GC)\xi(t) + Bu(t) + Gy(t), \\
u(t) &= F\xi(t),
\end{aligned}
\tag{8}
$$

where F is any map such that $A + BF$ is a stability matrix and G is any map such that $A - GC$ is a stability matrix.

The controller (8) is an *observer-based dynamic feedback controller*, since it is composed of a state observer and a static feedback part.

Summary and Future Directions

We have given an introduction to observer-based feedback controllers and have explained that such controllers are dynamic feedback controllers that can be represented as the composition of a state observer for the system, together with a static control law mimicking a (not permitted) static state feedback control law. We have given a detailed description of this principle for the case that the system to be controlled has no external disturbances or reference signals and the control objective is internal stability of the system. More intricate versions of the principle of observer-based feedback control appear in control design problems for linear systems with external disturbances and reference signals and with different, more sophisticated, control objectives. Examples

of these are the regulator problem, the problem of disturbance decoupling with internal stability, the $\mathcal{H}_2$ optimal control problem, and the $\mathcal{H}_\infty$ suboptimal control problem.

Abstract

Observers are objects delivering estimation of variables which cannot be directly measured. The access to such *hidden* variables is made possible by combining modeling and measurements. But this is bringing face to face real world and its abstraction with, as a result, the need for dealing with uncertainties and approximations leading to difficulties in implementation and convergence.

Keywords

Introduction

Observers are answers to the question of estimating, from observed/measured/empirical variables, denoted y, and delivered by sensors equipping a real-world system, some "theoretical" variables, called hidden variables in this text, denoted z, which are involved in a mathematical model related to this system. The measured variables make what is called the a posteriori information on the hidden variables, whereas the model is part of the a priori information. Because a model cannot fit exactly a system, introduction of uncertainties is mandatory.

Typically this model describing the link between hidden and measured variables is made of three components:

- *A dynamic model* describes the dynamics/evolution ($\dot{x}$ denotes the time derivative $\frac{dx}{dt}$):

$$\dot{x}(t) = f(x(t), t, \delta^s(t)) \text{ resp. } x_{k+1} = f_k\left(x_k, \delta^s_k\right), \tag{1}$$

where t, in the continuous case, or k, in the discrete case, is an evolution parameter, called time in this text; x is a state, assumed finite dimensional in this text; and δ^s represents the uncertainties in the state dynamics. Any possible known inputs are represented here by the time dependence of f.

- *A sensor model* relates state and measured variables:

$$y(t) = h\left(x(t), t, \delta^m(t)\right) \text{ resp. } y_k = h_k\left(x_k, \delta^m_k\right) \tag{2}$$

with δ^m representing the uncertainties in the measurements.

- A model which relates state and hidden variables:

$$z(t) = \mathcal{U}\left(x, t, \delta^h(t)\right) \text{ resp. } z_k = \mathcal{U}_k\left(x_k, \delta^h_k\right) \tag{3}$$

where again δ^h represents the uncertainties in the hidden variables.

In a deterministic setting, the a priori information on the uncertainties $(\delta^s, \delta^m, \delta^h)$ may be that the values of δ^s, δ^m, and δ^h are unknown but belong to known sets Δ^s, Δ^m, and Δ^h. Namely, we have:

O

$$\delta^s(t) \in \Delta^s(t), \; \delta^m(t) \in \Delta^m(t), \delta^h(t) \in \Delta^h(t) \,,$$
$$\text{respectively}, \delta_k^s \in \Delta_k^s \,, \; \delta_k^m \in \Delta_k^m \,, \; \delta_k^h \in \Delta_k^h \,. \tag{4}$$

In a stochastic setting and more specifically in a Bayesian approach, it may be that δ^s, δ^m, and δ^h are unknown realizations of stochastic processes for which we know the probability distributions.

Similarly we may also know a priori that we have:

$$\begin{aligned} & x(t) \in \mathcal{X}(t), && z(t) \in \mathcal{Z}(t) \\ \text{respectively}, \quad & x_k \in \mathcal{X}_k, && z_k \in \mathcal{Z}_k \end{aligned} \tag{5}$$

where the sets $\mathcal{X}$ and $\mathcal{Z}$ are known or we may have a priori probability distribution for x and z.

In this context, the a priori information is the data of the functions f, h, and $\mathcal{Y}$, of the sets Δ^s, Δ^m, and Δ^h or the corresponding probability distribution and so may be also of the sets $\mathcal{X}$ and $\mathcal{Z}$ or the corresponding a priori probability distribution.

In the next section, we state the observation problem and give the solutions which are direct consequences of the deterministic and stochastic setting given above. This will allow us to see that an observer is actually a dynamical system with the measurements as inputs and the estimate as output. But approximations in the implementation of these solutions, not knowing how to initialize, may lead to convergence problems even when the uncertainties disappear. The second part of this text is devoted to this convergence topic.

To ease the presentation, we deal only with the discrete time case in section "Set Valued and Conditional Probability Valued Observers" and the continuous time case in sections "An Optimization Approach" and "Convergent Observers."

Observation Problem and Its Solutions

The Observation Problem

Let $X^{\delta^s}(x, t, s)$, respectively $X_l^{\delta^s}(x, k)$, denote a solution of (1) at time s, respectively l, going through x at time t, respectively k, and under the action of δ^s.

Observation problem *At each time t, respectively k, given the function $s \in]t - T, t] \mapsto y(s)$, respectively the sequence $l \in \{k - K, \dots, k\} \mapsto y_l$, find an estimation $\hat{z}(t)$, respectively $\hat{z}_k$, of $z(t)$, respectively, z_k, satisfying*

$$\hat{z}(t) = \mathcal{Y}\left(\hat{x}(t), t, \delta^h(t)\right) \; resp. \; \hat{z}_k = \mathcal{Y}_k\left(\hat{x}_k, \delta_k^h\right) \,.$$

where $\hat{x}(t)$, respectively $\hat{x}_k$, is to be found as a solution of

$$\hat{x}(t) \in \mathcal{X}(t) \,,$$
$$y(s) = h\left(X^{\delta^s}(\hat{x}(t), t, s), s, \delta^m(s)\right) \; \forall s \in]t - T, t],$$

respectively

$$\hat{x}_k \in \mathcal{X}_k \,,$$
$$y_l = h_l\left(X_l^{\delta^s}(\hat{x}_k, k), \delta_l^m\right) \; \forall l \in \{k - K, \dots, k\}$$

and where the time functions δ^s, δ^m, and δ^h must agree with the a priori (deterministic/stochastic) information or minimized in some way.

In this statement T, respectively K, quantifies the time window length or memory length during which we record the measurement. The accumulation with time of measurements, together with the model equations (1)–(3) and the assumptions on $(\delta^s, \delta^m, \delta^h)$, gives a redundancy of data compared with the number of unknowns that the hidden variables are. This is why it may be possible to solve this observation problem.

To simplify the following presentation, we restrict our attention on the case where the hidden variables are actually the full model state, i.e.,

$$z = \mathcal{Y}(x) = x \,.$$

When z differs from x, observers are called functional observers.

Set-Valued and Conditional Probability-Valued Observers

Conceptually the answer to this problem is easy at least when the memory increases with time ($\dot{T}(t) = 1$ resp. $K_{k+1} = K_k + 1$) leading to an infinite non-fading memory. It consists in starting

from all what the a priori information makes possible and to eliminate what is not consistent with the a posteriori information. In the set-valued observer setting, in the discrete time case, this gives the following observer. To ease its reading, we underline the data given by the a priori information. It requires the introduction of two sets ξ_k and $\xi_{k|k-1}$ which are updated at each time k when a new measurement y_k is made available. ξ_k is the set which x_k is guaranteed to belong to at time k, knowing all the measurements up to time k, and $\xi_{k|k-1}$ is the same but with measurements known up to time $k-1$.

Set-valued observer:

Initialization: $\quad\quad\quad \xi_0 = \underline{\mathcal{X}_0}$

At each time k: prediction (flowing) $\quad \xi_{k|k-1} = \underline{f_{k-1}}(\xi_{k-1}, \underline{\Delta^s_{k-1}})$

restriction (consistency) $\quad \xi_k = \big\{x \in \big(\xi_{k|k-1} \bigcap \underline{\mathcal{X}_k}\big) :$

$$y_k \in \underline{h_k}(x, \underline{\Delta^m_k})\big\}$$

estimation $\quad\quad\quad\quad \hat{x}_k \in \xi_k$

A key feature here is that *this observer has a state ξ_k – a set – and is a dynamical system in the form:*

$$\xi_{k+1} = \varphi_k(\xi_k, y_k), \quad\quad \hat{x}_k \in \xi_k$$

with y as input and $\hat{x}$ as output which is not single valued. Important also, the initial condition of the state ξ is given by the a priori information.

In the stochastic setting, following the Bayesian paradigm, the observer has the same structure but with the state ξ_k being a conditional probability. See Jazwinski (2007, Theorem 6.4) or Candy (2009, Table 2.1). In that setting too the observer is not a single state; it is the (a posteriori) conditional probability of the random variable x_k given the a priori information and the sequence of measurements $l \in \{k-K, \ldots, k\} \mapsto y_l$.

Comments

Implementation: For the time being, except for very specific cases (Kalman filter, . . .), the set-valued and the conditional probability-valued observers remain conceptual since we do not know how to manipulate numerically sets and probability laws. Their implementation requires approximations. For instance, see

Milanese et al. (1996) and Witsenhausen (1966) for the set case and Arulampalam et al. (2002), Bucy and Joseph (1987), Candy (2009), and Jazwinski (2007) for the conditional probability case.

Need of finite or infinite but fading memory: In these observers, model states x which are consistent with the a priori information but do not agree with the a posteriori information are eliminated (set intersection or probability product). But once a point is eliminated, this is forever. As a consequence if there is, at some time, a misfit between a priori and a posteriori information, it is mistakenly propagated in future times. A way to round this problem is to keep the information memory finite or infinite but fading. In particular, with fixed length memory, consistent points which were disregarded due to measurements which are no more in the memory are reintroduced. This says also that observers should not be sensitive to their initial condition.

Not single-valued estimate. The observers introduced above realize a lossless data compression with extracting and preserving all what concerns the hidden variables in the redundant data given by a priori and a posteriori information. But this "lossless compression" answer is not single valued (set valued or conditional probability valued) as a result of taking uncertainties into account. Actually, to get a single-valued answer, *the observation problem must be complemented by making precise for what the estimation is made.* For instance, we may want to select the most likely or the average or more generally some cost-minimizing estimate $\hat{x}$ among all the possible ones given by ξ. In this way we obtain an observer giving a single-valued estimate:

$$\xi_{k+1} = \varphi_k(\xi_k, y_k), \quad\quad \hat{x}_k = \tau_k(\xi_k)$$

respectively

$$\dot{\xi}(t) = \varphi(\xi(t), y(t), t), \quad \hat{x}(t) = \tau(\xi(t), t) \tag{6}$$

But then, in general, we lose information, and in particular we have no idea on the confidence

level this estimate has. Also, since the function τ, at least, encodes for what the estimate $\hat{x}$ is used, for different uses, different functions τ may be needed.

An Optimization Approach

A shortcut to obtain directly an observer giving a single-valued estimate is to design it by trading off among a priori and a posteriori information (see Cox 1964, pages 7–10; Alamir 2007). For example, in the continuous time case, we can select the estimate $\hat{x}(t)$ among the minimizers (in x) of

$$\mathcal{C}(\{s \mapsto \delta^s(s)\}, x, t) = \int_{-\infty}^{t} C\left(\delta^s(s), y(s),\right.$$
$$\left. X^{\delta^s}(x, t, s), s\right) ds$$

where $X^{\delta^s}(x, t, s)$ is still the notation for a solution to (1) and $\{s \mapsto \delta^s(s)\}$, representing the unmodelled effect on the dynamics, is among the arguments for the minimization. The infinitesimal cost C is chosen to take nonnegative values and be such that $C(0, h(x, s), x, s)$ is zero. For instance, it can be

$$C(\delta^s, y, x, s) = \|\delta^s\|_x^2 + d_y(y, h(x, s))^2$$

where $\|.\|_x$ is a norm at the point x and d_y is a distance in the measurement space. In the same spirit, instead of optimization, a minimax approach can be followed. See, for instance, Bertsekas and Rhodes (1971), Başar and Bernhard (1995, Chapter 7), and Willems (2004).

With x fixed, the minimization of $\mathcal{C}$ is an infinite horizon optimal control problem in reverse time. Solving on line this problem is extremely difficult and again approximations are needed. We do not go on with this approach, but we remark that, under extra assumptions, the observer we obtain following this approach can also be implemented in the form of a dynamical system (6) but with the specificity that *the estimate $\hat{x}$ is part of the observer state ξ and its dynamics are a copy of the undisturbed model with a correction term which is zero when the estimated*

state reproduces the measurement. Namely, we get

$$\dot{\hat{x}}(t) = f(\hat{x}(t), t, 0) + E\Big(\{\sigma \mapsto y(\sigma)\}, \hat{x}(t), y(t), t\Big)$$

where E is zero when $h(\hat{x}(t), t) = y(t)$. But, as opposed to what we saw in the previous section, the initial condition for the part $\hat{x}$ of the observer state is unknown. Hence, we encounter again the need for the observer to forget its initial condition.

Convergent Observers

We have mentioned that often an observer can be implemented as a dynamical system, but without knowing necessarily how to initialize it. Also approximation is involved both in its design and its implementation. So, at least when it gives a single-valued estimate, we are facing the problem of convergence of this estimate to the "true" value, at least when there is no uncertainties. We concentrate now our attention on the study of this convergence, but, to simplify, in the continuous time case only.

Let the model and observer dynamics be

$$\dot{x}(t) = f(x(t), t), \quad y(t) = h(x(t), t) \quad (7)$$

$$\dot{\xi} = \varphi(\xi(t), y(t), t), \quad \hat{x}(t) = \tau(\xi(t), y(t), t) \tag{8}$$

with the observer state ξ of finite dimension m. We denote by $(X(x, t, s), \Xi((x, \xi), t, s))$ a solution of (7)–(8).

Since we are dealing with convergence, the focus is on what is going on when the time becomes very large and in particular on the set Ω of model states which are accumulation points of some solution. Specifically we are interested in the stability properties of the set

$$\mathfrak{Z}(t) = \Big\{(x, \xi) : x \in \Omega \,\&\, x = \tau(\xi, h(x, t), t)\Big\}$$

which is contained in the zero estimation error set associated with the given model-observer pair.

Definition 1 (convergent observer) We say the observer (8) is convergent if for each t, there

exists a set $\mathfrak{Z}_a(t) \subset \mathfrak{Z}(t)$, such that on the domain of existence of the solution, a distance between the point $(X(x,t,s), \Xi((x,\xi),t,s))$ and the set $\mathfrak{Z}_a(s)$ is upperbounded by a real function $s \mapsto \beta^c_{x,\xi,t}(s)$, may be dependent on (x,ξ,t), with nonnegative values, strictly decreasing and going to zero as s goes to infinity.

Necessary Conditions for Observer Convergence

No Restriction on τ

It is possible to prove that *if the observer is convergent, then,*

- *Necessity of detectability:* When h and τ are uniformly continuous in x and ξ, respectively, the estimate $\hat{x}$ does converge to the model state x. In this case, two solutions of the model (7) which produce the same measurement must converge to each other. This is an asymptotic distinguishability property called detectability. If we are interested not only in the asymptotic behavior but also in the transient (as for output feedback), a property stronger than detectability is needed. In particular instantaneous distinguishability (see section "Observers Based on Instantaneous Distinguishability") is necessary if we want to be able to impose the decay rate of the function $\beta^c_{x,\xi,t}$.

- *Necessity of $m \geq n - p$:* For each t, there exists a subset $\mathcal{X}_a(t)$ of Ω, supposed to collect the model states which can be asymptotically estimated and such that we can associate, to each of its point x, a set $\tau^i(x,t)$ allowing us to redefine the set $\mathfrak{Z}_a(t)$ as

$$\mathfrak{Z}_a(t) = \left\{ (x,\xi) : \ x \in \mathcal{X}_a(t) \ \& \ \xi \in \tau^i(x,t) \right\} .$$

This implies that for each t and each x in $\mathcal{X}_a(t)$, there is a point ξ satisfying

$$x = \tau(\xi, h(x,t), t) . \tag{9}$$

This is a surjectivity property of the function τ but of a special kind since $h(x,t)$ is an argument of τ. We say that, for each t, *the function τ is surjective to $\mathcal{X}_a(t)$ given h.* In a "generic" situation this property requires the dimension m of the observer state ξ to be larger or equal to the dimension n of the model state x minus the dimension p of the measurement y.

τ Is Injective Given h

We consider now the case where the observer has been designed with a function τ which is injective given h, namely, we have the following implication, when x is in $\mathcal{X}_a(t)$,

$$\Big[\tau(\xi_1, h(x,t), t) = \tau(\xi_2, h(x,t), t)$$
$$\& \ \xi_1 \in \tau^i(x,t) \Big]$$
$$\implies \quad \xi_1 = \xi_2 .$$

In a "generic" situation, this property, together with the surjectivity given h, implies that the dimension m of the observer state ξ should be between $n - p$ and n.

If a convergent observer has such a function τ, then $(x,t) \mapsto \tau^i(x,t)$, which is (of course) a (single valued) function, admits a Lie derivative $(L_f \tau^i(x,t) = \lim_{dt \to 0} \frac{\tau^i(X(x,t,t+dt),t+dt) - \tau^i(x,t)}{dt})$ $L_f \tau^i$ satisfying

$$L_f \tau^i(x,t) = \varphi(\tau^i(x,t), h(x,t), t) \ \forall x \in \mathcal{X}_a(t) \tag{10}$$

This says (very approximatively) that φ is nothing but the image of the vector field f, under the change of coordinates $(x,t) \mapsto (\tau^i(x,t), t)$ but again all this given h. As partly obtained in the optimization approach, the observer dynamics are then a copy of the model dynamics with maybe a correction term which is zero when the estimated state reproduce the measurement.

If moreover the functions h and τ are uniformly continuous in x and ξ, respectively, then, given ξ_1 and ξ_2 a distance between $\Xi((x,\xi_1),t,s)$ and $\Xi((x,\xi_2),t,s)$ goes to zero as s goes to infinity. This property is related to what was called extreme stability (see Yoshizawa 1966) in the 1950s and 1960s and is called incremental stability today (see Angeli 2002). It holds when, with denoting by $\Xi^y(\xi,t,s)$ the solution at time s of the observer dynamics :

O

$$\dot{\xi}(t) \; = \; \varphi(\xi(t), y(t), t)$$

going through ξ at time t and under the action of y, *the flow $\xi \; \mapsto \; \Xi^y(\xi, t, s)$ is a strict contraction (see Jouffroy (2005) for a bibliography on contraction) for each $s > t$ or, at least, if a distance between any two solutions $\Xi^y(\xi_1, t, s)$ and $\Xi^y(\xi_2, t, s)$, with the same input y, converges to* 0.

Sufficient Conditions

Knowing now how a convergent observer should look like, we move to a quick description of some such observers.

Observers Based on Contraction

Since the flow generated by the observer should be a contraction, we may start its design by picking the function φ as

$$\dot{\xi}(t) \; = \; \varphi(\xi(t), y(t), t) \; = \; A\,\xi(t) \, + \, B(y(t), t)$$

where A, not related to f, is a matrix whose eigenvalues have strictly negative real part. Under weak restriction, there exists a function τ^i satisfying (10), namely,

$$L_f \tau^i(x, t) \; = \; A\, \tau^i(x, t) \, + \, B(h(x, t), t) \,. \tag{11}$$

To obtain a convergent observer, it is then sufficient that there exists a (uniformly continuous) function τ satisfying

$$x \; = \; \tau(\tau^i(x, t), h(x, t), t)$$

For this to be possible, the function τ^i should be injective given h. This injectivity holds when the observer state has dimension $m \geq 2(n + 1)$, the model is distinguishable, and provided the eigenvalues of A have a sufficiently negative real part and are not in a set of zero Lebesgue measure.

Unfortunately, we are facing again a possible difficulty in the implementation since an expression for a function τ^i satisfying (11) is needed and the function $\tau : (\xi, y, t) \mapsto \hat{x}(t)$ is known implicitly only as

$$\xi \; = \; \tau^i(\hat{x}(t), t) \,.$$

See Andrieu and Praly (2006), Luenberger (1964), and Shoshitaishvili (1990).

Observers Based on Instantaneous Distinguishability

Instantaneous distinguishability means that we can distinguish as quickly as we want two model states by looking at the paths of the measurements they generate. A sufficient condition to have this property can be obtained by looking at the Taylor expansion in s of $h(X(x, t, s), s)$. Indeed, we have:

$$h(X(x, t, s), s) = \sum_{i=0}^{m-1} h_i(x, t) \frac{(s - t)^i}{i!}$$
$$+ o\left((s - t)^{m-1}\right)$$

where h_i is a function obtained recursively as

$$h_0(x, t) \; = \; h(x, t)$$
$$h_{i+1}(x, t) \; = \; \widehat{\dot{h_i(x, t)}} \; = \; \frac{\partial h_i}{\partial x}(x, t) f(x, t) \\ + \frac{\partial h_i}{\partial t}(x, t).$$

If there exists an integer m such that, in some uniform way with respect to t, the function

$$x \; \mapsto \; H_m(x, t) = (h_0(x, t), \, \ldots, \, h_{m-1}(x, t))$$

is injective, then we do have instantaneous distinguishability. We say the system is differentially observable of order m when this injectivity property holds. When a system has such a property, the model state space has a very specific structure as discussed in Isidori (1995, Section 1.9). It means that we can reconstruct x from the knowledge of y and its $m-1$ first time derivatives, i.e., there exists a function Φ such that we have:

$$x \; = \; \Phi\left(H_m(x, t), t\right).$$

This way, we are left with estimating the derivatives of y. This can be done as follows. With the notation $\eta_i \; = \; h_{i-1}(x, t)$, we obtain:

$$\dot{\eta}(t) \;=\; F\,\eta + G\,h_m\big(\Phi(\eta(t),t)\,,\,t\big)$$

where

$$F\,\eta = (\eta_2,\,\ldots\,,\eta_m,\,0),\ \ G = (0,\,\ldots\,,0,\,1).$$

When the last term on the right hand side is Lipschitz, we can find a convergent observer in the form:

$$\dot{\xi}(t) = F\,\xi(t) + G\,h_m\,(\hat{x}(t),t) + K(y(t) - \xi_1(t)),$$
$$\hat{x}(t) = \tau\,(\xi(t),t),$$

with ξ being actually an estimation of η and where K is a constant matrix and τ is a modified version of Φ keeping the estimated state in its a priori given set $\mathcal{X}(t)$.

This is the high-gain observer paradigm. See Gauthier and Kupka (2001) and Tornambe (1988). The implementation difficulty is in the function $\hat{\Phi}$, not to mention sensitivity to measurement uncertainty.

Observers with τ Bijective Given h

Case Where τ Is the Identity Function A convergent observer whose function τ is the identity has the following form:

$$\dot{\xi} = f(\xi,t)$$
$$+ E\left(\{\sigma \mapsto y(\sigma)\}, \xi(t), y(t), t\right), \hat{x}(t) = \xi(t).$$
$$(12)$$

The only piece remaining to be designed is the correction term E. It has to ensure convergence and may be also other properties like symmetry preserving (see Bonnabel et al. 2008).

For this design, a first step is to exhibit some specific properties of the vector field f by writing it in some appropriate coordinates. For example, there may exist coordinates such that the expression of f takes the form $\mathfrak{f}(x(t), h(x,t), t)$ and the corresponding observer (12) is such that there exists a positive definite matrix P for which the function $s \mapsto (X(x,t,d) - \hat{X}((x,\hat{x}),t,s))' P(X(x,t,d) - \hat{X}((x,\hat{x}),t,s))$ is strictly decaying (if not zero). A necessary condition for this to be possible is that $\mathfrak{f}$ is

monotonic tangentially to the level sets of the function h, i.e., for all (x,y,v,t) satisfying $y = h(x,t)$ and $\frac{\partial h}{\partial x}(x,t)v = 0$, we have:

$$v^T P\,\frac{\partial \mathfrak{f}}{\partial x}(x,y,t)\,v \;\leq\; 0. \qquad (13)$$

This is another way of expressing a detectability condition. This expression is coordinate dependent, hence the importance of choosing the coordinates properly.

When this condition is strict and uniform in t, it is sufficient to get a locally convergent observer and even a nonlocal one when h is linear in x, i.e., $h(x,t) = H(t)x$, again a coordinate-dependent condition. In this latter case the observer takes the form

$$\dot{\xi}(t) = \mathfrak{f}(\xi(t), y(t), t) \;+\; \ell(\xi(t))\,P^{-1}H(t)^T$$
$$[y(t) - H(t)\xi(t)],$$
$$\hat{x}(t) = \xi(t),$$

where ℓ is a real function to be chosen with sufficiently large values. If (13) is strict and uniform and holds for all v, the correction term is not needed.

There are many other results of this type, exploiting one or the other specificity of the dependence on x of the function $\mathfrak{f}$ – monotonicity, convexity, ... See Fan and Arcak (2003), Krener and Isidori (1983), Respondek et al. (2004), Sanfelice and Praly (2012), ...

Case Where $(x,t) \mapsto (\tau^i(x,t), h(x,t), t)$ Is a Diffeomorphism At each time t we know already that the model state x we want to estimate satisfy $y(t) = h(x,t)$. So, as remarked in Luenberger (1964), when $(h(x,t), t)$ can be used as part of coordinates for (x,t), we need to estimate the remaining part only. This can be done if we find a function τ^i, whose values are $n - p$ dimensional, such that $(x,t) \mapsto (y,\eta,t) = (h(x,t), \tau^i(x,t), t)$ is a diffeomorphism and the flow $\eta \mapsto \eta^y(\eta,t,s)$ generated by

$$\dot{\eta}(t) = \frac{\partial \tau^i}{\partial x}(x(t),t)f(x(t),t) \;+\; \frac{\partial \tau^i}{\partial t}(x(t),t),$$
$$= \varphi(\eta(t), y(t), t)$$

is a strict contraction for all $s > t$. Indeed in this case the observer dynamics can be chosen as

$$\dot{\xi}(t) \;=\; \varphi(\xi(t), y(t), t)$$

and the estimate $\hat{x}(t)$ is obtained as solution of

$$\tau^i(\hat{x}(t), t) \;=\; \xi(t), \qquad h(\hat{x}(t), t) \;=\; y(t).$$

This is the reduced-order observer paradigm. See, for instance, Besançon (2000, Proposition 3.2), Carnevale et al. (2008), and Luenberger (1964, Theorem 4).

Abstract

Observers are dynamical systems which process the input and output signals of a given dynamical system and deliver an online estimate of the internal state of the given system which asymptotically converges to the exact value of the state. For linear, finite-dimensional, time-invariant systems, observers can be designed provided a weak observability property, known as detectability, holds.

Keywords

Linear systems; Observers; Reduced order observer; State estimation

Introduction

Consider a linear, finite-dimensional, time-invariant system described by equations of the form

$$\sigma x = Ax + Bu,$$
$$y = Cx + Du, \tag{1}$$

with $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, $y(t) \in \mathbb{R}^p$ and A, B, C, and D matrices of appropriate dimensions and with constant entries, and the problem of estimating its state from measurements of the input and output signals. In Eq. (1) $\sigma x(t)$ stands for $\dot{x}(t)$, if the system is continuous-time, and for $x(t + 1)$, if the system is discrete-time. In addition, if the system is continuous-time, then $t \in \mathbb{R}^+$, i.e., the set of nonnegative real numbers, whereas if the system is discrete-time, then $t \in Z^+$, i.e., the set of nonnegative integers.

We are interested in determining an online estimate $x_e(t) \in \mathbb{R}^n$, i.e., the estimate at time t has to be a function of the available information (input and output) at the same time instant. This implies that the estimate is generated by means of a device (known as filter) processing the current input and output of the system and generating a state estimate. The filter may be instantaneous, i.e., the estimate is generated instantaneously by processing the available information. In this case we have a static filter. Alternatively, the state estimate can be generated processing the available information through a dynamical device. In this case we have a dynamic filter.

Assume, for simplicity, that $D = 0$. This assumption is without loss of generality. In fact, if $y = Cx + Du$ and u are measurable, then also $\tilde{y} = Cx$ is measurable. Assume, in addition, that the filter which generates the online estimate is linear, finite-dimensional, and time-invariant. Then we may have the following two configurations:

- *Static filter.* The state estimate is generated via the relation

$$x_e = My + Nu, \tag{2}$$

  with M and N constant matrices of appropriate dimensions. The resulting interconnected system is described by the equations

$$\sigma x = Ax + Bu,$$
$$x_e = MCx + Nu. \tag{3}$$

- *Dynamic filter.* The state estimate is generated by the system

$$\sigma\xi = F\xi + Ly + Hu,$$
$$x_e = M\xi + Ny + Pu, \tag{4}$$

with F, L, H, M, N and P constant matrices of appropriate dimensions. The resulting interconnected system is described by the equations

$$\sigma x = Ax + Bu,$$
$$\sigma\xi = F\xi + LCx + Hu, \tag{5}$$
$$x_e = M\xi + NCx + Pu.$$

In what follows we study in detail the dynamic filter configuration. This is mainly due to the fact that this configuration allows us to solve most estimation problems for linear systems. Moreover, while the use of a static filter is very appealing, it provides a useful alternative only in very specific situations.

State Observer

A state observer is a filter that allows to estimate, asymptotically or in finite time, the state of a system from measurements of the input and output signals.

The simplest possible observer can be constructed considering a copy of the system, the state of which has to be estimated. This means that a candidate observer for system (1) is given by

$$\sigma\xi = A\xi + Bu$$
$$x_e = \xi. \tag{6}$$

To assess the properties of this candidate state observer, let $e = x - x_e$ be the estimation error and note that $\sigma e = Ae$. As a result, if $e(0) = 0$, then $e(t) = 0$ for all t and for any input signal u. However, if $e(0) \neq 0$, then, for any input signal u, $e(t)$ is bounded only if the system (1) is stable and converges to zero only if the system (1) is asymptotically stable. If these conditions do not hold, the estimation error is not bounded and system (6) does not qualify as a state observer for system (1). The intrinsic limitation of the observer (6) is that it does not use all the available information, i.e., it does not use the knowledge of

the output signal y. This observer is therefore an open-loop observer.

To exploit the knowledge of y, we modify the observer (6) adding a term which depends upon the available information on the estimation error, which is given by $y_e = Cx_e - y$. This modification yields a candidate state observer described by

$$\sigma\xi = A\xi + Bu + Ly_e,$$
$$x_e = \xi. \tag{7}$$

To assess the properties of this candidate state observer, note that $e = x - x_e$ is such that

$$\sigma e = (A + LC)e. \tag{8}$$

The matrix L (known as output injection gain) can be used to shape the dynamics of the estimation error. In particular, we may select L to assign the characteristic polynomial $p(s)$ of $A + LC$. To this end, note that

$$p(s) = \det(sI - (A + LC)) = \det(sI - (A' + C'L')).$$

Hence, there is a matrix L which arbitrarily assigns the characteristic polynomial of $A + LC$ if and only if the system

$$\sigma\xi = A'\xi + C'v$$

is reachable or, equivalently, if and only if the system (1) is observable.

We summarize the above discussion with two formal statements.

Proposition 1 *Consider system (1) and suppose the system is observable. Let $p(s)$ be a monic polynomial of degree n. Then there is a matrix L such that the characteristic polynomial of $A + LC$ is equal to $p(s)$. Note that for single-output systems, the matrix L assigning the characteristic polynomial of $A + LC$ is unique.*

Proposition 2 *System (1) is observable if and only if it is possible to arbitrarily assign the eigenvalues of $A + LC$.*

Detectability

The main goal of a state observer is to provide an online estimate of the state of a system. This goal may be achieved, as discussed in the previous section, if the system is observable. However, observability is not necessary to achieve this goal: in fact the unobservable modes are not modified by the output injection gain. This implies that there exists a matrix L such that system (8) is asymptotically stable if and only if the unobservable modes of system (1) have negative real part, in the case of continuous-time systems, or have modulo smaller than one, in the case of discrete-time systems. To capture this situation, we introduce a new definition.

Definition 1 (Detectability) System (1) is detectable if its unobservable modes have negative real part, in the case of continuous-time systems, or have modulo smaller than one, in the case of discrete-time systems.

Example 1 (Deadbeat observer) Consider a discrete-time system described by equations of the form

$$x(t+1) = Ax(t) + Bu(t),$$
$$y(t) \;\;= Cx(t),$$

and the problem of designing a state observer, described by the equation (7), such that, for any initial condition $x(0)$ and for any u, $e(k) = 0$, for all $k \geq N$, and for some $N > 0$. A state observer achieving this goal is called a deadbeat state observer. To achieve this goal, it is necessary to select L such that $(A + LC)^N = 0$ or, equivalently, such that the matrix $A + LC$ has all eigenvalues equal to 0. Note that $N \leq n$.

Reduced Order Observer

We have shown that, under the hypotheses of observability or detectability, it is possible to design an asymptotic observer of order n for the system (1). However, this observer is somewhat oversized, i.e., it gives an estimate for the n components of the state vector, without making use of the fact that some of these components can be directly determined from the output function, e.g., if $y = x_1$ there is no need to reconstruct x_1. It makes, therefore, sense to design a *reduced order observer*, i.e., a device that estimates only the part of the state vector which is not directly attainable from the output. To this end consider the system (1) with $D = 0$ and assume that the matrix C has p independent rows. This is the case if rank $C = p$, whereas if rank $C < p$ it is always possible to eliminate redundant rows. Then there exists a matrix Q such that, possibly after reordering the state variables,

$$QC = [I \;\; C_2].$$

Let

$$v = Qy = QCx = x_1 + C_2x_2,$$

in which $x_1(t) \in \mathbb{R}^p$ and $x_2(t) \in \mathbb{R}^{n-p}$ denote the first p and the last $n - p$ components of $x(t)$. Observe that the vector v is measurable.

From the definition of v, we conclude that if v and x_2 are known, then x_1 can be easily computed, i.e., there is no need to construct an observer for x_1.

Define now the new coordinates

$$\begin{bmatrix} \hat{x}_1 \\ \hat{x}_2 \end{bmatrix} = Tx = \begin{bmatrix} I & C_2 \\ 0 & I \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$$

and note that, by construction, $v = Qy = \hat{x}_1$. In the new coordinates, the system, with output v, is described by equations of the form

$$\sigma\hat{x}_1 = \tilde{A}_{11}\hat{x}_1 + \tilde{A}_{12}\hat{x}_2 + \tilde{B}_1u,$$
$$\sigma\hat{x}_2 = \tilde{A}_{21}\hat{x}_1 + \tilde{A}_{22}\hat{x}_2 + \tilde{B}_2u,$$
$$v \;\;= \hat{x}_1.$$

O

To construct an observer for $\hat{x}_2$, consider the system

$$\sigma\xi = F\xi + Hv + Gu,$$

with state ξ, driven by u and v, and with output

$$w = \xi + Lv.$$

The idea is to select the matrices F, H, G, and L in such a way that w be an estimate for $\hat{x}_2$. Let $w - \hat{x}_2$ be the observation error. Then

$$
\begin{aligned}
\sigma w - \sigma\hat{x}_2 = \quad & F\xi + Hv + Gu + L\left[\tilde{A}_{11}\hat{x}_1 + \tilde{A}_{12}\hat{x}_2 + \tilde{B}_1 u\right] - \left[\tilde{A}_{21}\hat{x}_1 + \tilde{A}_{22}\hat{x}_2 + \tilde{B}_2 u\right] \\
= \quad & F\xi + \left(H + L\tilde{A}_{11} - \tilde{A}_{12}\right)\hat{x}_1 + \left[L\tilde{A}_{12} - \tilde{A}_{22}\right]\hat{x}_2 + \left[G + L\tilde{B}_1 - \tilde{B}_2\right]u. \quad (9)
\end{aligned}
$$

To have convergence of the estimation error to zero, regardless of the initial conditions and of the input signal, we must have

$$\sigma(w - \hat{x}_2) = F(w - \hat{x}_2) \qquad (10)$$

and F must have all eigenvalues with negative real part, in the case of continuous-time systems, or with modulo smaller than one, in the case of discrete-time systems. Comparing Eqs. (9) and (10), we obtain that the matrices F, H, G, and L must be such that

$$L\tilde{A}_{12} - \tilde{A}_{22} = -F,$$
$$H + L\tilde{A}_{11} - \tilde{A}_{21} = FL,$$
$$G + L\tilde{B}_1 - \tilde{B}_2 = 0.$$

We now show how the previous equations can be solved and how the stability condition of F can be enforced. Detectability of the system implies that the (reduced system) $\sigma\tilde{\xi} = \tilde{A}_{22}\tilde{\xi}$ with output $\tilde{y} = \tilde{A}_{12}\tilde{\xi}$ is detectable. As a result, there exists a matrix L such that the matrix

$$F = \tilde{A}_{22} - L\tilde{A}_{12}$$

has all eigenvalues with negative real part, in the case of continuous-time systems, or with modulo smaller than one, in the case of discrete-time systems. Then the remaining equations are solved by

$$H = FL - L\tilde{A}_{11} + \tilde{A}_{21},$$
$$G = -L\tilde{B}_1 + \tilde{B}_2.$$

Finally, from $\hat{x}_1 = v$ and the estimate w of $\hat{x}_2$, we build an estimate x_e of the state x inverting the transformation T, i.e.,

$$
\begin{bmatrix} x_{1e} \\ x_{2e} \end{bmatrix} = \begin{bmatrix} I & -C_2 \\ 0 & I \end{bmatrix} \begin{bmatrix} v \\ w \end{bmatrix}.
$$

Summary and Future Directions

The problem of estimating the state of a linear system from input and output measurements can be solved provided a weak observability condition holds. The problem addressed in this entry is the simplest possible estimation problem: the underlying system is linear and all variables are exactly measured. Observers for nonlinear systems and in the presence of signals *corrupted* by noise can also be designed exploiting some of the basic ingredients, such as the notions of error system and of output injection, discussed in this entry.

Optimal Control and Mechanics

Anthony Bloch
Department of Mathematics, The University of Michigan, Ann Arbor, MI, USA

Abstract

There are very natural close connections between mechanics and optimal control as both involve variational problems. This is a huge subject and we just touch on some interesting connections here. A survey and history may be found in Sussman and Willems (1997). Other aspects may be found in Bloch (2003).

Keywords

Nonholonomic integrator; Sub-Riemannian optimal control; Variational problems

Variational Nonholonomic Systems and Optimal Control

Variational nonholonomic problems (i.e., constrained variational problems) are equivalent to optimal control problems under certain regularity conditions. This issue was investigated in Bloch and Crouch (1994), employing the classical results of Rund (1966) and Bliss (1930), which relate classical constrained variational problems to Hamiltonian flows, although not optimal control problems. We outline the simplest relationship and refer to Bloch (2003) for more details.

Let Q be a smooth manifold and TQ its tangent bundle with coordinates $(q^i, \dot{q}^i)$. Let $L : TQ \to \mathbb{R}$ be a given smooth Lagrangian and let $\Phi : TQ \to \mathbb{R}^{n-m}$ be a given smooth function. We consider the classical Lagrange problem:

$$\min_{q(\cdot)} \int_0^T L(q, \dot{q}) dt \qquad (1)$$

subject to the fixed endpoint conditions $q(0) = 0$, $q(T) = q_T$ and subject to the constraints

$$\Phi(q, \dot{q}) = 0.$$

Consider a modified Lagrangian $\Lambda(q, \dot{q}, \lambda) = L(q, \dot{q}) + \lambda \cdot \Phi(q, \dot{q})$ with Euler–Lagrange equations

$$\frac{d}{dt} \frac{\partial \Lambda}{\partial \dot{q}}(q, \dot{q}, \lambda) - \frac{\partial \Lambda}{\partial q}(q, \dot{q}, \lambda) = 0, \ \ \Phi(q, \dot{q}) = 0.$$
$$(2)$$

We can rewrite this equation in Hamiltonian form and show that the resulting equations are equivalent to the equations of motion given by the maximum principle for a suitable optimal control problem. Set $p = \frac{\partial \Lambda}{\partial \dot{q}}(q, \dot{q}, \lambda)$ and consider this equation together with the constraints $\Phi(q, \dot{q}) = 0$. We can solve these two equations for $(\dot{q}, \lambda)$ under suitable conditions as discussed in Bloch (2003). We obtain the standard Hamiltonian equations with $H(q, p) = p \cdot \phi(q, p) - L(q, \phi(q, p))$.

We now compare this to the optimal control problem

O

$$\min_{u(\cdot)} \int_0^T g(q, u) dt \qquad (3)$$

subject to $q(0) = 0$, $q(T) = q_T$, $\dot{q} = f(q, u)$, where $u \in \mathbb{R}^m$ and f, g are smooth functions.

Then we have the following:

Theorem 1 *The Lagrange problem and optimal control problem generate the same (regular) extremal trajectories, provided that:*

 (i) $\Phi(q, \dot{q}) = 0$ *if and only if there exists a u such that* $\dot{q} = f(q, u)$.
 (ii) $L(q, f(q, u)) = g(q, u)$.

For the proof and more details, see Bloch (2003).

The n-Dimensional Rigid Body

An interesting mechanical example is the n-dimensional rigid body. See Manakov (1976) and Ratiu (1980).

One can introduce a related system which we will call *the symmetric representation of the rigid body*; see Bloch et al. (2002).

By definition, ***the left invariant representation of the symmetric rigid body system*** is given by the first-order equations

$$\dot{Q} = Q\Omega; \qquad \dot{P} = P\Omega \qquad (4)$$

where $Q, P \in \mathrm{SO}(n)$ and where Ω is regarded as a function of Q and P via the equations

$$\Omega := J^{-1}(M) \in \mathfrak{so}(n) \quad \text{and} \quad M := Q^T P - P^T Q.$$

One can check that differentiating M yields the classical form of the n-dimensional rigid body equations. For more on the precise relationship, see Bloch et al. (2002).

Now we can link the symmetric representation of the rigid body equations with the theory of optimal control. This work, developed in Bloch and Crouch (1996) and more generally in Bloch et al. (2002), has been further extended to optimal control problems for the infinitesimal generators of group actions (so-called Clebsch optimal control problems) in Gay-Balmaz and Ratiu (2011) and Bloch et al. (2011, 2013) and even further to

a class of embedded control problems in Bloch et al. (2011, 2013).

Let $T > 0$, $Q_0, Q_T \in \mathrm{SO}(n)$ be given and fixed. Let the rigid body optimal control problem be given by

$$\min_{U \in \mathfrak{so}(n)} \frac{1}{4} \int_0^T \langle U, J(U) \rangle dt \qquad (5)$$

subject to the constraint on U that there be a curve $Q(t) \in \mathrm{SO}(n)$ such that

$$\dot{Q} = QU \qquad Q(0) = Q_0, \qquad Q(T) = Q_T. \qquad (6)$$

Proposition 1 *The rigid body optimal control problem has optimal evolution equations (4) where P is the costate vector given by the maximum principle.*

The optimal controls in this case are given by

$$U = J^{-1}(Q^T P - P^T Q). \qquad (7)$$

Kinematic Sub-Riemannian Optimal Control Problems

Optimal control of underactuated kinematic systems give rise to very interesting mechanical systems.

The problem is referred to as sub-Riemannian in that it gives rise to a geodesic flow with respect to a singular metric (see the work of Strichartz (1983, 1987) and Montgomery (2002) and references therein). This problem has an interesting history in control theory (see Brockett 1973, 1981; Baillieul 1975). See also Bloch et al. (1994) and Sussmann (1996) and further references below.

We consider control systems of the form

$$\dot{x} = \sum_{i=1}^m X_i u_i, \quad x \in M, \quad u \in \Omega \subset \mathbb{R}^m, \quad (8)$$

where Ω contains an open subset that contains the origin, M is a smooth manifold of dimension n, and each of the vector fields in the collection $F := \{X_1, \ldots, X_k\}$ is complete.

We assume that the system satisfies the accessibility rank condition and is thus controllable, since there is no drift term. Then we can pose the optimal control problem

$$\min_{u(\cdot)} \int_0^T \frac{1}{2} \sum_{i=1}^m u_i^2(t) dt \qquad (9)$$

subject to the dynamics (8) and the endpoint conditions $x(0) = x_0$ and $x(T) = x_T$. These problems were studied by Griffiths (1983) from the constrained variational viewpoint and from the optimal control viewpoint by Brockett (1981, 1983). In the sub-Riemannian geodesic problem, abnormal extremals play an important role. See work by Strichartz (1983), Montgomery (1994, 1995), Sussmann (1996), and Agrachev and Sarychev (1996).

Example: Optimal Control and a Particle in a Magnetic Field The control analysis of the Heisenberg model or nonholonomic integrator goes back to Brockett (1981) and Baillieul (1975), while a modern treatment of the relationship with a particle in a magnetic field may be found in Montgomery (1993), for example. A nice treatment of the pure mechanical aspects of a particle in a magnetic field may be found in Marsden and Ratiu (1999).

The Heisenberg optimal control equations are a particular case of planar charged particle motion in a magnetic field. This may be seen by considering the slightly more general problem below.

We now consider the optimal control problem

$$\min \int (u^2 + v^2) dt \qquad (10)$$

subject to the equations

$$\dot{x} = u,$$
$$\dot{y} = v,$$
$$\dot{z} = A_1 u + A_2 v, \qquad (11)$$

where $A_1(x, y)$ and $A_2(x, y)$ are smooth functions of x and y. $A_1 = y$ and $A_2 = -x$ recover the Heisenberg/nonholonomic integrator equations. More generally we get the flow of a particle in a magnetic field – it is not hard to carry out the optimal control analysis to see this. Details are in Bloch (2003).

Optimal Control and Pontryagin's Maximum Principle

Richard B. Vinter
Imperial College, London, UK

Abstract

Pontryagin's Maximum Principle is a collection of conditions that must be satisfied by solutions of a class of optimization problems involving dynamic constraints called optimal control problems. It unifies many classical necessary conditions from the calculus of variations. This article provides an overview of the Maximum Principle, including free-time and nonsmooth versions. A time-optimal control problem is solved as an example to illustrate its application.

Dynamic constraints; Hamiltonian system; Maximum principle; Nonlinear systems; Optimization

Optimal Control

A widely used framework for studying minimization problems, encountered in the optimal selection of flight trajectories and other areas of advanced engineering design and operation involving dynamic constraints, is to view them as special cases of the problem:

$$
(P) \begin{cases}
\text{Minimize } J(x(.), u(.)) : \\
= \int_0^T L(t, x(t), u(t))dt + g(x(0), x(T)) \\
\text{over measurable functions } u(.) : \\
\quad [0, T] \to R^m \text{ and} \\
\quad \text{absolutely continuous functions } x(.) : \\
\quad [0, T] \to R^n \text{ satisfying} \\
\dot{x}(t) = f(t, x(t), u(t)) \text{ a.e.,} \\
u(t) \in \Omega \text{ a.e.,} \\
(x(0), x(T)) \in C,
\end{cases}
$$

the data for which comprise a number $T > 0$, functions $f : [0, T] \times R^n \times R^m \to R^n$, $L : [0, T] \times R^n \times R^m \to R$ and $g : R^n \times R^n \to R$ and sets $C \subset R^n$ and $\Omega \subset R^m$.

It is assumed that set C has the functional inequality and equality constraint set representation

$$C = \{(x_0, x_1) \in R^n : \phi^i(x_0, x_1) \leq 0 \\ \text{for } i = 1, 2, \ldots, k_1 \text{ and} \quad (1) \\ \psi^i(x_0, x_1) = 0 \quad \text{for } i = 1, 2, \ldots, k_2 \},$$

in which $\phi^i : R^n \times R^n \to R$, $i = 1, \ldots, k_1$ and $\psi^i : R^n \times R^n \to R$, $i = 1, \ldots, k_2$ are given functions.

A control function is a measurable function $u(.) : [0, T] \to R^m$ satisfying $u(t) \in \Omega$ a.e. $t \in [0, T]$ A state trajectory $x(.)$ associated with a control function $u(.)$ is a solution to the differential equation $\dot{x}(t) = f(t, x(t), u(t))$. A pair of functions $(x(.), u(.))$ comprising a control function $u(.)$ and an associated state trajectory $x(.)$ satisfying the condition $(x(0), x(T)) \in C$ is a feasible process. A feasible process $(\bar{x}(.), \bar{u}(.))$ which achieves the minimum of $J(x(.), u(.))$ over all feasible processes is called a minimizer.

Frequently, the initial state is fixed, i.e., C takes the form

$C = \{x_0\} \times C_1$ for some $x_0 \in R^n$ and some $C_1 \subset R^n$.

In this case, (P) is a minimization problem over control functions. Allowing freedom in the choice of initial state introduces a flexibility into the formulation which is useful in some applications however.

Optimization problems involving dynamic constraints (such as, but not exclusively, those expressed as controlled differential equations) are known as optimal control problems. Various frameworks are available for studying such problems. (P) is of special importance, since it embraces a wide range of significant dynamic optimization problems which are beyond the reach of traditional variational techniques and, at the same time, it is well suited to the

derivation of general necessary conditions of optimality.

The Maximum Principle

The centerpiece of optimal control theory is a set of conditions that a minimizer $(\bar{x}(.), \bar{u}(.))$ must satisfy, known as Pontryagin's Maximum Principle or, simply, the Maximum Principle. It came to prominence through a 1961 book, which appeared in English translation as Pontryagin LS et al. (1962). It bears the name of L S Pontryagin, because of his role as leader of the research group at the Steklov Institute, Moscow, which achieved this advance. But the first proof is attributed to Boltyanskii. For given $\lambda \geq 0$, define the Hamiltonian function $H_\lambda : [0, T] \times R^n \times R^n \times R^m \to R'$

$$H_\lambda(t, x, p, u) := p^T f(t, x, u) - \lambda L(t, x, u).$$

Theorem 1 (The Maximum Principle) *Let $(\bar{x}(.), \bar{u}(.))$ be a minimizer for (P). Assume that the following hypotheses are satisfied:*

(i) g is continuously differentiable.

(ii) ϕ^i, $i = 1, \ldots, k_1$ and ψ^i, $i = 1, \ldots, k_2$, are continuously differentiable.

(iii) With $\tilde{f}(t, x, u) = (L(t, x, u), f(t, x, u))$, $\tilde{f}(., ., .)$ is continuous, $\tilde{f}(t, ., u)$ is continuously differentiable for each (t, u), and there exist $\epsilon > 0$ and $k(.) \in L^1$ such that

$$|\tilde{f}(t, x, u) - \tilde{f}(t, x', u)| \leq k(t)|x - x'|$$

for all $x, x' \in R^n$ such that $|x - \bar{x}(t)| \leq \epsilon$ and $|x' - \bar{x}(t)| \leq \epsilon$, and $u \in \Omega$, a.e. $t \in [0, T]$

(iv) Ω is a Borel set.

Then, there exist a number λ ($\lambda = 0$ or 1), an absolutely continuous arc $p : [0, T] \to R^n$, numbers $\alpha^i \geq 0$ for $i = 1, \ldots, k_1$ and numbers β^i for $i = 1, \ldots, k_2$ satisfying

$$(p(.), \lambda, \{\alpha^i\}, \{\beta^i\}) \neq (0, 0, \{0, \ldots 0\}, \{0, \ldots 0\})$$

and such that the following conditions are satisfied:

The Adjoint Equation:

$$-\dot{p}(t) = \frac{\partial}{\partial x} f^T(t, \bar{x}(t), \bar{u}(t)) p(t)$$

$$-\lambda \frac{\partial}{\partial x} L^T(t, \bar{x}(t), \bar{u}(t)), \quad a.e.,$$

The Maximization of the Hamiltonian Condition:

$$H_\lambda(t, \bar{x}(t), p(t), \bar{u}(t))$$

$$= \max_{u \in \Omega} H_\lambda(t, \bar{x}(t), p(t), u) \quad a.e.,$$

The Transversality Condition:

$$(p^T(0), -p^T(T)) = \lambda \nabla g(\bar{x}(0), \bar{x}(T))$$

$$+ \sum_{i=1}^{k_1} \alpha^i \nabla \phi^i(\bar{x}(0), \bar{x}(T))$$

$$+ \sum_{i=1}^{k_2} \beta^i \nabla \psi^i(\bar{x}(0), \bar{x}(T))$$

and $\alpha^i = 0$ *for all* $i \in \{1, \ldots, k_1\}$ *such that* $\phi^i(\bar{x}(0), \bar{x}(T)) < 0,$ *in which*

$$\nabla h(x_0, x_1)(\bar{x}_0, \bar{x}_1):$$

$$= \left[\frac{\partial}{\partial x_0} h(\bar{x}_0, \bar{x}_1), \frac{\partial}{\partial x_1} h(\bar{x}_0, \bar{x}_1) \right]. \quad (2)$$

If the functions $L(t, x, u)$ *and* $f(t, x, u)$ *are independent of t, then also*

Constancy of the Hamiltonian for Autonomous Problems:

$$H_\lambda(\bar{x}(t), p(t), \bar{u}(t)) = c \quad a.e.$$

for some constant c.

We allow the cases $k_1 = 0$ (no inequality constraints) and $k_2 = 0$ (no equality endpoint constraints). In the first case, the non-degeneracy condition becomes $(p(.), \lambda, \{\beta^i\}) \neq (0, 0, 0)$ and the summation involving the α^i's is dropped from the transversality condition. The second case, or any combination of the two cases, is treated similarly.

Derivation of the costate equation and boundary conditions. A simple way to derive the differential equations for the $p_i(.)$'s is, first, to construct the Hamiltonian $H_\lambda(t, x, p, u) = p^T f(t, x, u) p^T f(t, x, u) - \lambda L(t, x, u)$ and, second, to use the fact that the ith component $p_i(.)$ of the costate $p(t) = [p_1(t), \ldots, p_n(t)]^T$ satisfies the equation:

$$-\dot{p}_i(t) = \frac{\partial}{\partial x_i} H_\lambda(t, \bar{x}(t), p(t), \bar{u}(t))$$

$$\text{for } i = 1, \ldots, n.$$

The preceding equations are of course merely a component-wise statement of the costate equation above. In many applications the endpoint constraints take the form

$$x_i(0) = \xi_0^i \text{ for } i \in J_0 \text{ and } x_i(0) \in R^n \text{ for } i \notin J_0$$

$$x_i(T) = \xi_1^i \text{ for } i \in J_1 \text{ and } x_i(0) \in R^n \text{ for } i \notin J_1$$

for given index sets $J_0, J_1 \subset \{0, \ldots, n\}$ and n-vectors ξ_0^i for $i \in J_0$ and ξ_1^i for $i \in J_1$, i.e., the endpoints of each state trajectory component are either "fixed" or "free." In such cases the rules for setting up the boundary conditions on the $p_i(.)$'s are

$$p_i(0) \in R^n \text{ for } i \in J_0 \text{ and } p_i(0)$$

$$= \lambda \frac{\partial}{\partial x_{0i}} g(\bar{x}(0), \bar{x}(T)) \text{ for } i \notin J_0$$

$$p_i(T) \in R^n \text{ for } i \in J_1 \text{ and } -p_i(T)$$

$$= \lambda \frac{\partial}{\partial x_{1i}} g(\bar{x}(0), \bar{x}(T)) \text{ for } i \notin J_1,$$

i.e., if $x_i(0)$ (respectively $x_i(T)$) is fixed, then $p_i(0)$ (respectively $p_i(T)$) is free, and if $x_i(0)$ (respectively $x_i(T)$) is free, then $p_i(0)$ (respectively $p_i(T)$) is fixed.

The optimal control problem (P) is a generalization of the following problem in the calculus of variations:

$$\begin{cases} \text{Minimize } \int_0^T L(t, x(t), \dot{x}(t)) dt \\ \text{over absolutely continuous arcs } x(.): \\ \quad [0, T] \to R^n \text{ satisfying} \\ (x(0), x(T)) = (a, b). \end{cases} \quad (3)$$

for given $L : [0, T] \times R^n \times R^n \to R$ and $(a, b) \in R^n \times R^n$. This problem is a special case of (P) in which $f(t, x, u) = u$, $\Omega = R^n$, $k_1 = 0$, $k_2 = 2n$ and

$$\left((\psi^1(x_0, x_1), \ldots, \psi^n(x_0, x_1)), \right.$$
$$\left(\psi^{n+1}(x_0, x_1) \ldots, \psi^{2n}(x_0, x_1) \right)$$
$$= \left(x_0^T - a^T, x_1^T - b^T \right).$$

It is a straightforward exercise to deduce from the Maximum Principle, in this special case, that a minimizer satisfies the classical Euler–Lagrange and Weierstrass conditions and also that the minimizer and associate costate arc satisfy Hamilton's system of equations, under an additional uniform convexity hypothesis on $L(t, x, .)$. Thus, the Maximum Principle unifies many of the classical necessary conditions from the calculus of variations and, furthermore, validates them under reduced hypotheses. But it has far-reaching implications, beyond these conditions, because it allows the presence of pathwise constraints on the velocities, expressed in terms of a controlled differential equation and a control constraint set, which are encountered in engineering design, econometrics, and other areas.

The Hamiltonian System

In favorable circumstances, we are justified in setting the cost multiplier $\lambda = 1$ and, furthermore, the maximization of the Hamiltonian condition permits us, for each t, to express u as a function of x and p:

$$u = u^*(t, x, p).$$

The Maximum Principle now asserts that a minimizing arc $\bar{x}(.)$ is the first component of a pair of absolutely continuous functions $(\bar{x}(.), p(.))$ satisfying *Hamilton's system of equations*:

$$(-\dot{p}^T(t), \dot{\bar{x}}^T(t)) = \nabla_{xp} H_1(t, \bar{x}(t), p(t), u^*$$
$$(t, \bar{x}(t), p(t))) \quad \text{a.e.,} \quad (4)$$

in which $\nabla_{xp} H_1$ denotes the gradient of $H(t, x, p, u)$ w.r.t. the vector $[x^T, p^T]^T$ variable for fixed (t, u), together with the endpoint conditions

$$(\bar{x}(0), \bar{x}(T)) \in C \text{ and } (p^T(0), -p^T(T))$$
$$= \lambda \nabla g(\bar{x}(0), \bar{x}(T))$$
$$+ \sum_{i=1}^{k_1} \alpha^i \nabla \phi^i(\bar{x}(0), \bar{x}(T))$$
$$+ \sum_{i=1}^{k_2} \beta^i \nabla \psi^i(\bar{x}(0), \bar{x}(T)),$$

for some nonnegative numbers $\{\alpha^i\}$ and numbers $\{\beta^i\}$ satisfying

$$\alpha^i = 0 \quad \text{for all } i \in \{1, \ldots, k_1\} \text{ such that}$$
$$\times \phi^i(\bar{x}(0), \bar{x}(T)) < 0,$$

where ∇g, $\nabla \phi$ and $\nabla \psi$ etc., are as defined in (2). The minimizing control satisfies the relation

$$\bar{u}(t) = u^*(t, \bar{x}(t), p(t)).$$

Notice that the first-order vector differential equation (4) is a system of $2n$ scalar, first-order differential equations. Let us suppose that $\bar{k}_1$ inequality endpoint constraints are active at $(\bar{x}(0), \bar{x}(T))$. Then, satisfaction of the active constraints and the transversality condition impose $2n + \bar{k}_1 + k_2$ on the boundary values of $(\bar{x}(.), p(.))$. Taking account of the fact, however, that there are $\bar{k}_1 + k_2$ unknown endpoint multipliers, we see that the effective number of endpoint constraints accompanying the differential equation (4) is

$$2n + \bar{k}_1 + k_2 - (\bar{k}_1 + k_2) = 2n.$$

Thus, the set of $2n$ scalar first-order differential equations (4) defining the "two-point boundary value problem" to determine $(\bar{x}, p)$ has the "right" number of endpoint conditions.

Refinements

Free-Time Problems: Consider a variant on the "autonomous" case of problem (P) (L and f do not depend on t), call it (FT), in which the terminal time T is no longer fixed, but is a choice variable along with the control function and the initial state, and the cost function is

$$\tilde{J}(T, x(.), u(.))$$

$$:= \int_0^T L(x(t), u(t))dt + \tilde{g}(T, x(0), x(T))$$

for some function $\tilde{g}(.,.,.)$. Take a minimizer $(\bar{T}, \bar{x}(.), \bar{u}(.))$ for (FT). Assume, in addition to hypotheses (i)–(iii), that Ω is bounded and the function $k(.)$ in (iii) is bounded. Then the Maximum Principle conditions (for data in which the end time is frozen at $T = \bar{T}$) continue to be satisfied for some $p(.) : [0, \bar{T}] \to R^n$ and λ, including the constancy of the Hamiltonian condition

$$H_\lambda(\bar{x}(t), p(t), \bar{u}(t)) = c \quad \text{a.e } t \in [0, \bar{T}]$$

for some constant c. But a new condition is required to reflect the extra degree of freedom in the new problem specification, namely, the free end time. This is an additional transversality condition involving the constant value c of the Hamiltonian:

Free Time Transversality Condition: $c = \lambda \frac{\partial}{\partial T} g(\bar{T}, \bar{x}(0), \bar{x}(T))$.

Other Refinements: Versions of the Maximum Principle are available to take account of pathwise functional inequality constraints on state variables ("pure" state constraints) and of both state and control variables ("mixed" constraints). Maximum Principle-like conditions have also been derived for optimal control problems in which the dynamic constraint takes the form of a retarded differential equation with control terms and in which the class of control functions is enlarged to include Dirac delta functions ("impulse" optimal control problems).

The Nonsmooth Maximum Principle

In early derivations of the Maximum Principle, it was assumed that the functions $f(t, x, u)$ and $L(t, x, u)$ were continuously differentiable with respect to the x variable. A major research endeavor since the early 1970s has been to find versions of the Maximum Principle than remain valid when the functions $f(t, x, u)$ and $L(t, x, u)$ satisfy merely a "bounded slope" or, synonymously, a Lipschitz continuity condition with respect to x. Such functions are "nonsmooth" in the sense that they can fail to be differentiable, in the conventional sense, at some points in their domains. An overview of the Maximum Principle would be incomplete without reference to such advances.

The search for nonsmooth optimality conditions is motivated by a desire to solve optimal control problems where, in particular, the function $f(t, x, u)$ is a piecewise linear function of x (for fixed (t, u)). Such functions arise, for example, when the $f(t, x, u)$ is constructed empirically via a lookup table and linear interpolation. Nonsmooth cost integrands are encountered when they are constructed using "pointwise" supremum and/or "absolute value" operations. The function

$$J(x(.)) = \int_0^T |x(t)|dt + \max\{x(1), 0\},$$

which penalizes the L^1 norm of the state trajectory and the terminal value of the scalar state, but only if this is nonnegative, is a case in point.

When attempting to generalize the Maximum Principle to allow for nonsmooth data, we encounter the challenge of interpreting the adjoint equation, which can be written as

$$-\dot{p}(t) = \frac{\partial}{\partial x} H_\lambda(t, \bar{x}(t), \bar{u}(t) p(t)),$$

in circumstances when the x-gradients of f and L are not defined, at least not in a conventional sense. One approach to dealing with this problem is via the Clarke generalized gradient ∂m of function $m: R^n \to R$ at a point $\bar{x}$:

$\partial m(\bar{x}) := \text{co} \{\xi \mid$ there exist sequences $x^i \to \bar{x}$, $\xi^i \to \xi$ such that, for each i, $m(.)$ is Frêchet differentiable at x^i and $\xi_i = \frac{\partial}{\partial x} m(x^i)\}$.

Here, "co" means closed convex hull. In a landmark paper, Clarke FH 1976, Clarke proved a necessary condition commonly referred to as the nonsmooth Maximum Principle, in which the adjoint equation is replaced by a differential inclusion involving the (partial) generalized gradient $\partial_x H(t, \bar{x}(t), p(t), \bar{u}(t))$ of $H(t, ., p(t), \bar{u}(t))$ w.r.t x, evaluated at $\bar{x}(t)$, namely,

$$-\dot{p}^T(t) \in \partial_x H(t, \bar{x}(t), \bar{u}(t)) \quad \text{a.e. } t \in [0, T].$$

This formulation of the "adjoint inclusion" for the nonsmooth Maximum Principle and the unrestricted hypothesis under which it is derived in this paper remain state of the art.

Example

We illustrate the application of the Maximum Principle with a simple example. It has the following interpretation. A 1 kg mass is located 1 m along the line and has zero velocity. We seek a time $\bar{T} > 0$ s. which is the minimum over all times $T > 0$ having the property: there exists a time-varying force $u(t)$, $0 \le t \le 1$ satisfying

$$-1 \le u(t) \le +1$$

such that, under the action of the force, the mass is located at the origin with zero velocity at time T. Note that, in consequence of Newton's second law, the vector $x(t) = (x_1(t), x_2(t))$ comprising the displacement and velocity of mass satisfies

$$\begin{bmatrix} \dot{x}_1(t) \\ \dot{x}_2(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u(t). \tag{5}$$

This is a special case of the free-time problem

$$\begin{cases} \text{Minimize } T \\ \text{over times } T > 0, \text{ measurable functions } u(.): \\ \qquad [0, T] \to R \text{ and} \\ \qquad \text{absolutely continuous functions } x(.): \\ \qquad [0, T] \to R^2 \text{ such that} \\ \dot{x}(t) = Ax(t) + bu(t) \quad \text{a.e.} \\ u(t) \in \Omega \quad \text{a.e.} \\ (x_1(0), x_2(0)) = (1, 0) \quad \text{and} \\ \qquad (x_1(T), x_2(T)) = (0, 0). \end{cases}$$

in which $A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$, $b = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$ and $\Omega = [-1, +1]$.

The (free-time) Maximum Principle provides the following information about a minimizing end time $\bar{T}$, control $\bar{u}(.)$, and corresponding state $\bar{x}(.) = (\bar{x}_1(.), \bar{x}_2(.))$. There exists an arc $p(.) = [p_1(.), p_2(.)]^T$ such that

$$\dot{\bar{x}}_1(t) = \bar{x}_2(t) \quad \text{and} \quad \dot{\bar{x}}_2(t) = \bar{u}(t), \tag{6}$$

$$-\dot{p}_1(t) = 0 \quad \text{and} \quad -\dot{p}_2(t) = p_1(t), \tag{7}$$

$$\bar{u}(t) = \arg\max \{p_2(t)u \mid u \in [-1, +1]\} \tag{8}$$

$$(\bar{x}_1, \bar{x}_2)(0) = (1, 0) \text{ and } (\bar{x}_1, \bar{x}_2)(T) = (0, 0) \tag{9}$$

$$p_1(t)\bar{x}_2(t) + |p_2(t)| = \lambda \quad \text{for all } t. \tag{10}$$

Condition (1) permits us to express $\bar{u}(.)$ in terms of $p_2(.)$, thus

$$\bar{u}(t) = \text{sign}\{p_2(t)\},$$

and thereby eliminate $\bar{u}(.)$. It can be shown that relations (6)–(2) have a unique solution for $\bar{T}$, $\bar{u}(t)$, $\bar{x}(t)$, $p(t)$ and $\lambda = 0$ or 1. Furthermore, these relations cannot be satisfied with $\lambda = 0$. The unique solution (with $\lambda = 1$) is

$$\bar{T} = 2$$

$$(\bar{x}_1(t), \bar{x}_2(t))$$

$$= \begin{cases} (1 - \frac{1}{2}t^2, -t) & \text{if } t \in [0, 1) \\ (\frac{1}{2} - (t-1) + \frac{1}{2}(t-1)^2, \\ \quad -1 + \frac{1}{2}(t-1)) & \text{if } t \in [1, 2], \end{cases}$$

$$\bar{u}(t) = \begin{cases} -1 \text{ if } t \in [0, 1) \\ +1 \text{ if } t \in [1, 2], \end{cases}$$

$$p_1(t) = -1 \text{ and } p_2(t) = -1 + t \quad \text{for } t \in [0, 2].$$

The Maximum Principle is a necessary condition of optimality. Since a minimizer exists and since $(\bar{T}, \bar{x}(.), \bar{u}(.), p(.))$ is a unique solution to the Maximum Principle relations, it follows that $(\bar{T}, \bar{x}(.), \bar{u}(.))$ is the solution to the problem.

This problem is amenable to simpler, more elementary, solution techniques. But the above solution is enlightening, because it highlights important generic features of the Maximum Principle. We see how the "maximization of the Hamiltonian condition" can be used to eliminate the control function and thereby to set up a two-point boundary problem for $\bar{x}(.)$ and $p(.)$ (a very nonclassical construction).

Optimal Control and the Dynamic Programming Principle

Maurizio Falcone
Dipartimento di Matematica, SAPIENZA – Università di Roma, Rome, Italy

Abstract

This entry illustrates the application of Bellman's dynamic programming principle within the context of optimal control problems for continuous-time dynamical systems. The approach leads to a characterization of the optimal value of the cost functional, over all possible trajectories given the initial conditions, in terms of a partial differential equation called the Hamilton–Jacobi–Bellman equation. Importantly, this can be used to synthesize the corresponding optimal control input as a state-feedback law.

Keywords

Continuous-time dynamics; Hamilton–Jacobi–Bellman equation; Optimization; Nonlinear systems; State feedback

Introduction

The dynamic programming principle (DPP) is a fundamental tool in optimal control theory. It was largely developed by Richard Bellman

in the 1950s (Bellman 1957) and has since been applied to various problems in deterministic and stochastic optimal control. The goal of optimal control is to determine the control function and the corresponding trajectory of a dynamical system which together optimize a given criterion usually expressed in terms of an integral along the trajectory (the cost functional) (Fleming and Rishel 1975; Macki and Strauss 1982). The function which associates with the initial condition of the dynamical system the optimal value of the cost functional among all the possible trajectories is called the *value function*. The most interesting point is that via the dynamic programming principle, one can derive a characterization of the value function in terms of a nonlinear partial differential equation (the Hamilton–Jacobi–Bellman equation) and then use it to synthesize a feedback control law. This is the major advantage over the approach based on the Pontryagin Maximum Principle (PMP) (Boltyanskii et al. 1956; Pontryagin et al. 1962). In fact, the PMP merely gives necessary conditions for the characterization of the open-loop optimal control and of the corresponding optimal trajectory. The DPP has also been applied to construct approximation schemes for the value function although this approach suffers from the "curse of dimensionality" since one has to solve a nonlinear partial differential equation in a high dimension. Despite the elegance of the DPP approach, its practical application is limited by this bottleneck, and the solution of many optimal control problems has been accomplished instead via the two-point boundary value problem associated with the PMP.

The Infinite Horizon Problem

Let us present the main ideas for the classical *infinite horizon problem*. Let a controlled dynamical system be given by

$$\begin{cases} \dot{y}(s) = f(y(s), \alpha(s)) \\ y(t_0) = x_0. \end{cases} \quad (1)$$

where $x_0, y(s) \in \mathbb{R}^d$, and

$$\alpha : [t_0, T] \to A \subseteq \mathbb{R}^m,$$

with T finite or $+\infty$. Under the assumption that the control is measurable, existence and uniqueness properties for the solution of (1) are ensured by the Carathèodory theorem:

Theorem 1 (Carathèodory) *Assume that:*
1. *$f(\cdot, \cdot)$ is continuous.*
2. *There exists a positive constant $L_f > 0$ such that*

$$|f(x, a) - f(y, a)| \leq L_f |x - y|,$$

   for all $x, y \in \mathbb{R}^d$, $t \in \mathbb{R}^+$ and $a \in A$.
3. *$f(x, \alpha(t))$ is measurable with respect to t.*

   Then, there is a unique absolutely continuous function $y : [t_0, T] \to \mathbb{R}^d$ that satisfies

$$y(s) = x_0 + \int_{t_0}^{s} f(y(\tau), \alpha(\tau)) d\tau. \quad (2)$$

which is interpreted as the solution of (1).

Note that the solution is continuous, but only a.e. differentiable, so it must be regarded as a weak solution of (1). By the theorem above, fixing a control in the set of admissible controls

$$\alpha \in \mathcal{A} := \{\alpha : [t_0, T] \to A, \text{measurable}\}$$

yields a unique trajectory of (1) which is denoted by $y_{x_0, t_0}(s; \alpha)$. Changing the control policy generates a family of solutions of the controlled system (1) with index α. Since the dynamics (1) are "autonomous," the initial time t_0 can be shifted to 0 by a change of variable. So to simplify the notation for autonomous dynamics, we can set $t_0 = 0$ and we denote this family by $y_{x_0}(s; \alpha)$ (or even write it as $y(s)$ if no ambiguity over the initial state or control arises). It is customary in dynamic programming, moreover, to use the notations x and t instead of x_0 and t_0 (since x and t appear as variables in the Hamilton–Jacobi–Bellman equation).

Optimal control problems require the introduction of a *cost functional* $J : \mathcal{A} \to \mathbb{R}$ which is used to select the "optimal trajectory" for (1). In the case of the infinite horizon problem, we set $t_0 = 0$, $x_0 = x$, and this functional is defined as

O

$$J_x(\alpha) = \int_0^\infty g(y_x(s, \alpha), \alpha(s))e^{-\lambda s}\,ds \quad (3)$$

for a given $\lambda > 0$. The function g represents the *running cost* and λ is the *discount factor*, which can be used to take into account the reduced value, at the initial time, of future costs. From a technical point of view, the presence of the discount factor ensures that the integral is finite whenever g is bounded. Note that one can also consider the undiscounted problem ($\lambda = 0$) provided the integral is still finite. The goal of optimal control is to find an optimal pair (y^*, α^*) that minimizes the cost functional. If we seek optimal controls in open-loop form, i.e., as functions of t, then the Pontryagin Maximum Principle furnishes necessary conditions for a pair (y^*, α^*) to be optimal.

A major drawback of an open-loop control is that being constructed as a function of time, it cannot take into account errors in the true state of the system, due, for example, to model errors or external disturbances, which may take the evolution far from the optimal forecasted trajectory. Another limitation of this approach is that a new computation of the control is required whenever the initial state is changed.

For these reasons, we are interested in the so-called *feedback controls*, that is, controls expressed as functions of the state of the system. Under feedback control, if the system trajectory is perturbed, the system reacts by changing its control strategy according to the change in the state. One of the main motivations for using the DPP is that it yields solutions to optimal control problems in the form of feedback controls.

DPP for the Infinite Horizon Problem

The starting point of dynamic programming is to introduce an auxiliary function, the *value function*, which for our problem is

$$v(x) = \inf_{\alpha \in \mathcal{A}} J_x(\alpha), \quad (4)$$

where, as above, x is the initial position of the system. The value function has a clear meaning: it is the optimal cost associated with the initial

position x. This is a reference value which can be useful to evaluate the efficiency of a control – if $J_x(\bar{\alpha})$ is close to $v(x)$, this means that $\bar{\alpha}$ is "efficient."

Bellman's dynamic programming principle provides a first characterization of the value function.

Proposition 1 (DPP for the infinite horizon problem) *Under the assumptions of Theorem 1, for all $x \in \mathbb{R}^d$ and $\tau > 0$,*

$$v(x) = \inf_{\alpha \in \mathcal{A}} \left\{ \int_0^\tau g(y_x(s; \alpha), \alpha(s))e^{-\lambda s}\,ds \right.$$
$$\left. + e^{-\lambda \tau} v(y_x(\tau; \alpha)) \right\}. \quad (5)$$

Proof Denote by $\bar{v}(x)$ the right-hand side of (5). First, we remark that for any $x \in \mathbb{R}^d$ and $\bar{\alpha} \in \mathcal{A}$,

$$J_x(\bar{\alpha}) = \int_0^\infty g(\bar{y}(s), \bar{\alpha}(s))e^{-\lambda s}\,ds$$
$$= \int_0^\tau g(\bar{y}(s), \bar{\alpha}(s))e^{-\lambda s}\,ds$$
$$+ \int_\tau^\infty g(\bar{y}(s), \bar{\alpha}(s))e^{-\lambda s}\,ds$$
$$= \int_0^\tau g(\bar{y}(s), \bar{\alpha}(s))e^{-\lambda s}\,ds + e^{-\lambda \tau}$$
$$\times \int_0^\infty g(\bar{y}(s + \tau), \bar{\alpha}(s + \tau))e^{-\lambda s}\,ds$$
$$\geq \int_0^\tau g(\bar{y}(s), \bar{\alpha}(s))e^{-\lambda s}\,ds + e^{-\lambda \tau} v(\bar{y}(\tau))$$

(here, $y_x(s, \bar{\alpha})$ is abbreviated as $\bar{y}(s)$). Taking the infimum over all trajectories, first over the right-hand side and then the left of this inequality, yields

$$v(x) \geq \bar{v}(x) \quad (6)$$

To prove the opposite inequality, we recall that $\bar{v}$ is defined as an infimum, and so, for any $x \in \mathbb{R}^d$ and $\varepsilon > 0$, there exists a control $\bar{\alpha}_\varepsilon$ (and the corresponding evolution $\bar{y}_\varepsilon$) such that

$$\bar{v}(x) + \varepsilon \geq \int_0^\tau g(\bar{y}_\varepsilon(s), \bar{\alpha}_\varepsilon(s)) e^{-\lambda s} ds + e^{-\lambda \tau} v(\bar{y}_\varepsilon(\tau)). \tag{7}$$

On the other hand, the value function v being also defined as an infimum, for any $x \in \mathbb{R}^d$ and $\varepsilon > 0$, there exists a control $\tilde{\alpha}_\varepsilon$ such that

$$v(\bar{y}_\varepsilon(\tau)) + \varepsilon \geq J_{\bar{y}_\varepsilon(\tau)}(\tilde{\alpha}_\varepsilon). \tag{8}$$

Inserting (8) in (7), we get

$$\begin{aligned} \bar{v}(x) &\geq \int_0^\tau g(\bar{y}_\varepsilon(s), \bar{\alpha}_\varepsilon(s)) e^{-\lambda s} ds \\ &\quad + e^{-\lambda \tau} J_{\bar{y}_\varepsilon(\tau)}(\tilde{\alpha}_\varepsilon) - (1 + e^{-\lambda \tau}) \varepsilon \\ &\geq J_x(\hat{\alpha}) - (1 + e^{-\lambda \tau}) \varepsilon \\ &\geq v(x) - (1 + e^{-\lambda \tau}) \varepsilon, \end{aligned} \tag{9}$$

where $\hat{\alpha}$ is a control defined by

$$\hat{\alpha}(s) = \begin{cases} \bar{\alpha}_\varepsilon(s) & 0 \leq s < \tau \\ \tilde{\alpha}_\varepsilon(s - \tau) & s \geq \tau. \end{cases} \tag{10}$$

(Note that $\hat{\alpha}(\cdot)$ is still measurable). Since ε is arbitrary, (9) finally yields $\bar{v}(x) \geq v(x)$.

We observe that this proof crucially relies on the fact that the control defined by (10) still belongs to $\mathcal{A}$, being a measurable control. The possibility of obtaining an admissible control by joining together two different measurable controls is known as the *concatenation property*.

The Hamilton–Jacobi–Bellman Equation

The DPP can be used to characterize the value function in terms of a nonlinear partial differential equation. In fact, let $\alpha^* \in \mathcal{A}$ be the optimal control, and y^* the associated evolution (to simplify, we are assuming that the infimum is a minimum). Then,

$$v(x) = \int_0^\tau g(y^*(s), \alpha^*(s)) e^{-\lambda s} ds + e^{-\lambda \tau} v(y^*(\tau)),$$

that is,

$$v(x) - e^{-\lambda \tau} v(y^*(\tau)) = \int_0^\tau g(y^*(s), \alpha^*(s)) e^{-\lambda s} ds$$

so that adding and subtracting $e^{-\lambda \tau} v(x)$ and dividing by τ, we get

$$\begin{aligned} e^{-\lambda \tau} \frac{(v(x) - v(y^*(\tau)))}{\tau} &+ \frac{v(x)(1 - e^{-\lambda \tau})}{\tau} \\ &= \frac{1}{\tau} \int_0^\tau g(y^*(s), \alpha^*(s)) e^{-\lambda s} ds. \end{aligned}$$

Assume now that v is regular. By passing to the limit as $\tau \to 0^+$, we have

$$\lim_{\tau \to 0^+} -\frac{v(y^*(\tau)) - v(x)}{\tau}$$
$$= -Dv(x) \cdot \dot{y}^*(x) = -Dv(x) \cdot f(x, \alpha^*(0))$$

$$\lim_{\tau \to 0^+} v(x) \frac{(1 - e^{-\lambda \tau})}{\tau} = \lambda v(x)$$

$$\lim_{\tau \to 0^+} \frac{1}{\tau} \int_0^\tau g(y^*(s), \alpha^*(s)) e^{-\lambda s} ds = g(x, \alpha^*(0))$$

where we have assumed that $\alpha^*(\cdot)$ is continuous at 0. Then, we can conclude

$$\lambda v(x) - Dv(x) \cdot f(x, a^*) - g(x, a^*) = 0 \tag{11}$$

where $a^* = \alpha^*(0)$. Similarly, using the equivalent form

$$v(x) + \sup_{\alpha \in \mathcal{A}} \left\{ -\int_0^\tau g(y(s), \alpha(s)) e^{-\lambda s} ds \right.$$
$$\left. - e^{-\lambda \tau} v(y(\tau)) \right\} = 0$$

of the DPP and the inequality, this implies for any (continuous at 0) control $\alpha \in \mathcal{A}$,

$$\begin{aligned} \lambda v(x) &- Dv(x) \cdot f(x, a) - g(x, a) \\ &\leq 0, \quad \text{for every } a \in A. \end{aligned} \tag{12}$$

Combining (11) and (12), we obtain the *Hamilton–Jacobi–Bellman equation* (or *dynamic programming equation*):

$$\lambda u(x) + \sup_{a \in A} \{-f(x,a) \cdot Du(x) - g(x,a)\} = 0,$$
$$(13)$$

which characterizes the value function for the infinite horizon problem associated with minimizing (3). Note that given x, the value of a achieving the max (assuming it exists) corresponds to the control $a^* = \alpha^*(0)$, and this makes it natural to interpret the argmax in (13) as the optimal feedback at x (see Bardi and Capuzzo Dolcetta (1997) for more details).

In short, (13) can be written as

$$H(x,u,Du) = 0$$

with $x \in \mathbb{R}^d$, and

$$H(x,u,p) = \lambda u(x) + \sup_{a \in A} \{-f(x,a) \cdot p - g(x,a)\}.$$
$$(14)$$

Note that $H(x,u,\cdot)$ is convex (being the sup of a family of linear functions) and that $H(x,\cdot,p)$ is monotone (since $\lambda > 0$). It is also easy to see that the solution u is not differentiable even when f and g are smooth functions (i.e., $f, g, \in C^\infty(\mathbb{R}^n, A)$), so we need to deal with weak solution of the Bellman equation. This can be done in the framework of viscosity solutions, a theory initiated by Crandall and Lions in the 1980s which has been successfully applied in many areas as optimal control, fluid dynamics, and image processing (see the books Barles (1994) and Bardi and Capuzzo Dolcetta (1997) for an extended introduction and numerous applications to optimal control). Typically viscosity solutions are Lipschitz continuous solutions so they are differentiable almost everywhere.

An Extension to the Minimum Time Problem

In the minimum time problem, we want to minimize the time of arrival of the state on a given *target set* $\mathcal{T}$. We will assume that $\mathcal{T} \subset \mathbb{R}^d$ is a closed set. Then our cost functional will be given by

$$J(x,\alpha) = t_x(\alpha)$$

where

$$t_x(\alpha) := \begin{cases} \min\{t : y_x(t,\alpha) \in \mathcal{T}\} & \text{if } y_x(t,\alpha) \in \mathcal{T} \\ & \text{for some } t \geq 0 \\ +\infty & \text{if } y_x(t,\alpha) \notin \mathcal{T} \\ & \text{for any } t \geq 0 \end{cases}$$

The corresponding value function is called the *minimum time function*

$$T(x) := \inf_{\alpha(\cdot) \in \mathcal{A}} t_x(\alpha(\cdot)). \qquad (15)$$

The main difference with respect to the previous problem is that now the value function T will be finite valued only on a subset $\mathcal{R}$ which depends on the target, on the dynamics, and on the set of admissible controls.

Definition 1 The reachable set $\mathcal{R}$ is defined by

$$\mathcal{R} := \cup_{t>0} \mathcal{R}(t) = \{x \in \mathbb{R}^n : T(x) < +\infty\}$$

where, for $t > 0$, $\mathcal{R}(t) := \{x \in \mathbb{R}^n : T(x) < t\}$.

The meaning is clear: $\mathcal{R}$ is the set of initial points which can be driven to the target in finite time. The system is said to be *controllable* on $\mathcal{T}$ if for all $t > 0$, $\mathcal{T} \subset \text{int}(\mathcal{R}(t))$ (here, $\text{int}(D)$ denotes the interior of the set D). Assuming controllability in a neighborhood of the target one gets the continuity of the minimum time function and under the assumptions made on f, A, and $\mathcal{T}$, one can prove some interesting properties:

  (i) $\mathcal{R}$ is open.
 (ii) T is continuous on $\mathcal{R}$.
(iii) $\lim_{x \to x_0} T(x) = +\infty$, for any $x_0 \in \partial\mathcal{R}$.

Now let us denote by $\mathcal{X}_D$ the characteristic function of the set D. Using in $\mathcal{R}$ arguments similar to the proof of DPP in the previous section one can obtain the following DPP:

Proposition 2 (DPP for the minimum time problem) *For any $x \in \mathcal{R}$, the value function satisfies*

$$T(x) = \inf_{\alpha \in \mathcal{A}} \{t \wedge t_x(\alpha) + \mathcal{X}_{\{t \leq t_x(\alpha)\}} T(y_x(t,\alpha))\}$$
$$\text{for any } t \geq 0 \qquad (16)$$

and

$$T(x) = \inf_{\alpha \in \mathcal{A}} \{t + T(y_x(t, \alpha))\}$$

$$\text{for any } t \in [0, T(x)] \qquad (17)$$

From the previous DPP, one can also obtain the following characterization of the minimum time function.

Proposition 3 *Let* $\mathcal{R} \backslash \mathcal{T}$ *be open and* $T \in C(\mathcal{R} \backslash \mathcal{T})$*, then* T *is a viscosity solution of*

$$\max_{a \in A} \{-f(x, a) \cdot \nabla T(x)\} = 1 \qquad x \in \mathcal{R} \backslash \mathcal{T}$$

$$(18)$$

coupled with the natural boundary condition

$$\begin{cases} T(x) = 0 & x \in \partial \mathcal{T} \\ \lim_{x \to \partial \mathcal{R}} T(x) = +\infty \end{cases}$$

By the change of variable $v(x) = 1 - e^{-T(x)}$, one can obtain a simpler problem getting rid of the boundary condition on $\partial \mathcal{R}$ (which is unknown). The new function v will be the unique viscosity solution of an external Dirichlet problem (see Bardi and Capuzzo Dolcetta (1997) for more details), and the reachable set can be recovered a posteriori via the relation $\mathcal{R} = \{x \in \mathbb{R}^d : v(x) < 1\}$.

Further Extensions and Related Topics

The DPP has been extended from deterministic control problems to many other problems. In the framework of stochastic control problems where the dynamics are given by a diffusion, the characterization of the value function obtained via the DPP leads to a second-order Hamilton–Jacobi–Bellman equation (Fleming and Soner 1993; Kushner and Dupuis 2001). Another interesting extension has been made in differential games where the DPP is based on the delicate notion of nonanticipative strategies for the players and leads to a nonconvex nonlinear partial differential equation (the Isaacs equation)

(Bardi and Capuzzo Dolcetta 1997). For a short introduction to numerical methods based on DP and exploiting the so-called "value iteration," we refer the interested reader to the Appendix A in Bardi and Capuzzo Dolcetta (1997) and to Kushner and Dupuis (2001) (see also the book Howard (1960) for the "policy iteration").

Optimal Control via Factorization and Model Matching

Michael Cantoni
Department of Electrical & Electronic
Engineering, The University of Melbourne,
Parkville, VIC, Australia

Abstract

One approach to linear control system design involves the matching of certain input-output models with respect to a quantification of closed-loop performance. The approach is based on a parametrization of all stabilizing feedback controllers, which relies on the existence of coprime factorizations of the plant model. This parametrization and spectral factorization methods for solving model-matching problems are described within the context of impulse-response energy and worst-case energy-gain measures of controller performance.

Keywords

Coprime factorization; $\mathscr{H}_2$ control; $\mathscr{H}_\infty$ control; Spectral factorization; Youla-Kučera controller parametrization

Introduction

Various linear control problems can be formulated in terms of the interconnection shown in Fig. 1; e.g., see Francis and Doyle (1987), Boyd and Barratt (1991), and Zhou et al. (1996). The linear system K is a *controller* (with input y and output $u - v_1$) to be designed for the generalized *plant* model G. The latter is constructed so that controller *performance* (i.e., the quality of K relative to specifications) can be quantified as a nonnegative functional of

$$H(G, K) = G_{11} + G_{12}K(I - G_{22}K)^{-1}G_{21}, \tag{1}$$

which relates the input w and the output z when $v_1 = 0$ and $v_2 = 0$. The objective is to select K, to minimize this measure of performance. Alternatively, controllers that achieve a specified upper bound are sought. It is also usual to require *internal stability*, which pertains to the fictitious signals v_1 and v_2, as discussed more subsequently. The best known examples are $\mathscr{H}_2$ and $\mathscr{H}_\infty$ control problems. In the former, performance is quantified as the energy (resp. power) of z when w is impulsive (resp. unit white noise), and in the latter, as the worst-case energy gain from w to z, which can be used to reflect robustness to model uncertainty; see Zhou et al. (1996).

The special case of $G_{22} = 0$ gives rise to a (weighted) *model-matching* problem, in that the corresponding performance map $H(G, K) = G_{11} + G_{12}KG_{21}$ exhibits *affine* dependence on the design variable K, which is chosen to match $G_{12}KG_{21}$ to $-G_{11}$ with respect to the scalar quantification of performance. Any internally stabilizable problem with $G_{22} \neq 0$, can be converted into a model-matching problem. The key ingredients in this transformation are coprime factorizations of the plant model. The role of these and other factorizations in a model-matching approach to $\mathscr{H}_2$ and $\mathscr{H}_\infty$ control problems is the focus of this article.

For the sake of argument, finite-dimensional linear time-invariant systems are considered via real-rational transfer functions in the *frequency domain*, as the existence of all factorizations
Optimal Control via Factorization and Model Matching, Fig. 1 Standard interconnection for control system design

employed is well understood in this setting. Indeed, constructions via state-space realizations and Riccati equations are well known. The merits of the model-matching approach pursued here are at least twofold: (i) the underlying algebraic input-output perspective extends to more abstract settings, including classes of distributed-parameter and time-varying systems (Desoer et al. 1980; Vidyasagar 1985; Curtain and Zwart 1995; Feintuch 1998; Quadrat 2006); and (ii) model matching is a convex problem for various measures of performance (including mixed indexes) and controller constraints. The latter can be exploited to devise numerical algorithms for controller optimization (Boyd and Barratt 1991; Dahleh and Diaz-Bobillo 1995; Qi et al. 2004).

First, some notation regarding transfer functions and two measures of performance for control system design is defined. Coprime factorizations are then described within the context of a well-known parametrization of stabilizing controllers, originally discovered by Youla et al. (1976) and Kucera (1975). This yields an affine parametrization of performance maps for problems in standard form, and thus, a transformation to a model-matching problem. Finally, the role of spectral factorizations in solving model-matching problems with respect to impulse-response energy ($\mathscr{H}_2$) and worst-case energy-gain ($\mathscr{H}_\infty$) measures of performance is discussed.

Notation and Nomenclature

$\mathcal{R}$ generically denotes a linear space of matrices having fixed row and column dimensions, which are not reflected in the notation for convenience, and entries that are *proper* real-rational functions of the complex variable s; i.e., $\left(\sum_{k=1}^m b_k s^k\right) / \left(\sum_{k=1}^n a_k s^k\right)$ for sets of real coefficients $\{a_k\}_{k=1}^n$ and $\{b_k\}_{k=1}^m$ with $m \leq n < \infty$. The compatibility of matrix dimensions is implicitly assumed henceforth. All matrices in $\mathcal{R}$ have (nonunique) "state-space" realizations of the form $C(sI - A)^{-1}B + D$, where A, B, C and D are real valued matrices.

This form naturally arises in frequency-domain analysis of the *input-output* map associated with the time-domain model $\dot{x}(t) = Ax(t) + Bu(t)$, with initial condition $x(0) = 0$ and output equation $y(t) = Cx(t) + Du(t)$, where $\dot{x}$ denotes the time derivative of x and u is the input. The study of such linear time-invariant differential equation models via the Laplace transform and *multiplication* by real-rational transfer function matrices is fundamental in linear systems theory (Kailath 1980; Francis 1987; Zhou et al. 1996). $P \in \mathcal{R}$ has an inverse $P^{-1} \in \mathcal{R}$ if and only if $\lim_{|s| \to \infty} P(s)$ is a nonsingular matrix. The superscripts T and $*$ denote the transpose and complex conjugate transpose. For a matrix $Z = Z^*$ with complex entries, $Z > 0$ means $z^* Z z \geq \epsilon z^* z$ for some $\epsilon > 0$ and all complex vectors z of compatible dimension. $P^\sim(s) := P(-s)^T$, whereby $(P(j\omega))^* = P^\sim(j\omega)$ for all real ω with $j := \sqrt{-1}$. Zeros of transfer function denominators are called poles.

In subsequent sections, several subspaces of $\mathcal{R}$ are used to define and solve two standard linear control problems. The subspace $\mathcal{B} \subset \mathcal{R}$ comprises transfer functions that have no poles on the imaginary axis in the complex plane. For $P \in \mathcal{B}$, the scalar performance index

$$\|P\|_\infty := \max_{-\infty \leq \omega \leq \infty} \bar{\sigma}(P(j\omega)) \geq 0$$

is finite; the real number $\bar{\sigma}(Z)$ is the maximum singular value of the matrix argument Z. This index measures the worst-case energy-gain from an input signal u, to the output signal $y = Pu$. Note that $\|P\|_\infty < \gamma$ if and only if $\gamma^2 I - P^\sim(j\omega)P(j\omega) > 0$ for all $-\infty \leq \omega \leq \infty$.

The subspace $\mathcal{S} \subset \mathcal{B} \subset \mathcal{R}$ consists of transfer functions that have no poles with positive real part. A transfer function in $\mathcal{S}$ is called *stable* because the corresponding input-output map is causal in the time domain, as well as bounded-in-bounded-out (in various senses). If $P \in \mathcal{S}$ is such that $P^\sim P = I$, then it is called *inner*. If $P, P^{-1} \in \mathcal{S}$, then both are called *outer*.

Let $\mathcal{L}$ denote the subspace of *strictly-proper* transfer functions in $\mathcal{B}$; i.e., for all entries of the

matrix, the degree n of the denominator *exceeds* the degree m of the numerator. Observe that $P \in \mathcal{L}$ if and only if $P^\sim \in \mathcal{L}$. Moreover, $P_1 P_2 \in \mathcal{L}$ and $P_3 P_1 \in \mathcal{L}$ for all $P_1 \in \mathcal{L}$ and $P_i \in \mathcal{B}$, $i = 2, 3$. Now, for $P_1, P_2 \in \mathcal{L}$, define the inner-product

$$\langle P_1, P_2 \rangle := \frac{1}{2\pi} \int_{-\infty}^{\infty} \text{trace}(P_1^\sim(j\omega) P_2(j\omega)) d\omega < \infty$$

and the scalar performance index $\|P\|_2 := \sqrt{\langle P, P \rangle} \geq 0$ for $P \in \mathcal{L}$. This index equates to the root-mean-square (energy) measure of the impulse response and the covariance (power) of the output signal $y = Pu$, when the input signal u is unit white noise. By the properties $\text{trace}(Z_1 + Z_2) = \text{trace}(Z_1) + \text{trace}(Z_2)$ and $\text{trace}(Z_1 Z_2) = \text{trace}(Z_2 Z_1)$ of the matrix trace, it follows that $\langle P_1 + P_2, P_3 \rangle = \langle P_1, P_3 \rangle + \langle P_2, P_3 \rangle$ and

$$\langle P_1, P_2 P_3 \rangle = \langle P_2^\sim P_1, P_3 \rangle = \langle P_1 P_3^\sim, P_2 \rangle$$
$$= \langle P_3^\sim, P_1^\sim P_2 \rangle \text{ for } P_i \in \mathcal{L}, \; i = 1, 2, 3. \tag{2}$$

The (not closed) subspace $\mathcal{L} \subset \mathcal{B} \subset \mathcal{R}$ can be expressed as the direct sum $\mathcal{L} = \mathcal{H} + \mathcal{H}_\perp$, where $\mathcal{H} = \mathcal{L} \cap \mathcal{S}$ and $\mathcal{H}_\perp$ is the subspace of transfer functions in $\mathcal{L}$ that have no poles with negative real part. That is, given $P \in \mathcal{L}$, there is a unique decomposition $P = \boldsymbol{\Pi}_+(P) + \boldsymbol{\Pi}_-(P)$, with $\boldsymbol{\Pi}_+(P) \in \mathcal{H}$ and $\boldsymbol{\Pi}_-(P) \in \mathcal{H}_\perp$. Observe that $P \in \mathcal{H}$ if and only if $P^\sim \in \mathcal{H}_\perp$. It can be shown via Plancherel's theorem that $\langle P_1, P_2 \rangle = 0$ for $P_1 \in \mathcal{H}_\perp$ and $P_2 \in \mathcal{H}$. Finally, note that $P_1 P_2 \in \mathcal{H}$ and $P_3 P_1 \in \mathcal{H}$ for $P_1 \in \mathcal{H}$ and $P_i \in \mathcal{S}$, $i = 2, 3$.

Coprime and Spectral Factorizations

Given $P \in \mathcal{R}$, the factorizations $P = NM^{-1} = \tilde{M}^{-1}\tilde{N}$ are said to be (doubly) *coprime* over $\mathcal{S}$, if $N, M, \tilde{N}, \tilde{M}$ are all elements of $\mathcal{S}$ and there exist $U_0, V_0, \tilde{U}_0, \tilde{V}_0$ all in $\mathcal{S}$ such that

$$\begin{bmatrix} \tilde{V}_0 & -\tilde{U}_0 \end{bmatrix} \begin{bmatrix} M \\ N \end{bmatrix} = I \text{ and } \begin{bmatrix} -\tilde{N} & \tilde{M} \end{bmatrix} \begin{bmatrix} U_0 \\ V_0 \end{bmatrix} = I \tag{3}$$

hold; i.e., $\begin{bmatrix} M^T & N^T \end{bmatrix}$ and $\begin{bmatrix} -\tilde{N} & \tilde{M} \end{bmatrix}$ are right invertible in $\mathcal{S}$. Importantly, if the factorizations are coprime and $P \in \mathcal{S}$, then $M^{-1} = \tilde{V}_0 - \tilde{U}_0 P$ and $\tilde{M}^{-1} = V_0 - P U_0$ are in $\mathcal{S}$, as sums of products of transfer functions in $\mathcal{S}$; i.e., M and $\tilde{M}$ are outer. Doubly coprime factorizations over $\mathcal{S}$ always exist, but these are not unique. Constructions from state-space realizations can be found in Zhou et al. (1996, Chapter 6) and Francis (1987), for example. As mentioned above, coprime factorizations play a role in transforming a standard problem into the special case of a model matching problem, via the Youla-Kučera parametrization of internally stabilizing controllers presented in the next section.

Subsequently, a special coprime factorization proves to be useful. If $P^\sim(s)P(s) = M^{-\sim}(s)N^\sim(s)N(s)M^{-1}(s) > 0$ for s on the extended imaginary axis (i.e., for $s = j\omega$ with $-\infty \leq \omega \leq \infty$), then it is possible to choose the factor N to be inner. In this case, if P is also an element of $\mathcal{S}$, then $P = NM^{-1}$ is called an *inner-outer factorization*, and $P^\sim P = (M^{-1})^\sim M^{-1}$ is called a *spectral factorization*, since $M, M^{-1} \in \mathcal{S}$. More generally, if $\Xi = \Xi^\sim \in \mathcal{B}$ satisfies $\Xi(s) > 0$ for s on the extended imaginary axis, then there exists a (non-unique) spectral factor $\Sigma, \Sigma^{-1} \in \mathcal{S}$ such that $\Xi = \Sigma^\sim \Sigma$. Similarly, there exists a co-spectral factor $\tilde{\Sigma}, \tilde{\Sigma}^{-1} \in \mathcal{S}$ such that $\Xi = \tilde{\Sigma} \tilde{\Sigma}^\sim$. State-space constructions via Riccati equations can be found in Zhou et al. (1996, Chapter 13), for example.

Affine Controller/Performance-Map Parametrization

With reference to Fig. 1, a generalized plant model $G = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix} \in \mathcal{R}$ is said to be *internally stabilizable* if there exists a $K \in \mathcal{R}$ such that the nine transfer functions associated with the map from the vector of signals (w, v_1, v_2) to

the vector of signals (z, u, y), which includes the performance map $H(G, K) = G_{11} + G_{12}K(I - G_{22}K)^{-1}G_{21}$, are all elements of $\mathcal{S}$. Accounting in this way for the influence of the fictitious signals v_1 and v_2, and the behavior of the internal signals u and y, amounts to following requirement: Given minimal state-space realizations, any nonzero initial condition response decays exponentially in the time domain when G and K are interconnected according to Fig. 1 with $w = 0$, $v_1 = 0$ and $v_2 = 0$. Not every $G \in \mathcal{R}$ is internally stabilizable in the sense just defined; for example, take G_{11} to have a pole with positive real part and $G_{21} = G_{12} = G_{22} = 0$. A necessary condition for stabilizability is $(I - G_{22}K)^{-1} \in \mathcal{R}$; i.e., the inverse must be proper. The latter always holds if G_{22} is strictly proper, as assumed henceforth to simplify the presentation. It is also assumed that G is internally stabilizable.

It can be shown that G is internally stabilized by K if and only if the standard feedback interconnection of G_{22} and K, corresponding to $w = 0$ in Fig. 1, is internally stable. That is, if and only if the transfer function

$$\begin{bmatrix} I & -K \\ -G_{22} & I \end{bmatrix} \in \mathcal{R}, \qquad (4)$$

which relates u and y to v_1 and v_2 by virtue of the summing junctions at the interconnection points, has an inverse in $\mathcal{S}$; see Francis (1987, Theorem 4.2). Substituting the coprime factorizations $K = UV^{-1} = \tilde{V}^{-1}\tilde{U}$ and $G_{22} = NM^{-1} = \tilde{M}^{-1}\tilde{N}$, it follows that the inverse of (4) is an element of $\mathcal{S}$ if and only if

$$\begin{bmatrix} M & U \\ N & V \end{bmatrix}^{-1} \in \mathcal{S} \qquad \Leftrightarrow \qquad \begin{bmatrix} \tilde{V} & -\tilde{U} \\ -\tilde{N} & \tilde{M} \end{bmatrix}^{-1} \in \mathcal{S}. \tag{5}$$

The equivalent characterizations of internal stability in (5) lead directly to affine parametrizations of controllers and performance maps. Specifically, following the approach of Desoer et al. (1980), Vidyasagar (1985), and Francis (1987), suppose that the factorizations $G_{22} = NM^{-1} = \tilde{M}^{-1}\tilde{N}$ are *doubly coprime* in the

sense that (3) holds for some $U_0, V_0, \tilde{U}_0, \tilde{V}_0 \in \mathcal{S}$. Indeed, since $0 = G_{22} - G_{22} = \tilde{M}^{-1}(\tilde{M}N - \tilde{N}M)M^{-1}$, it follows that

$$\begin{bmatrix} \tilde{V}_0 & -\tilde{U}_0 \\ -\tilde{N} & \tilde{M} \end{bmatrix} \begin{bmatrix} M & U_0 \\ N & V_0 \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}$$

$$= \begin{bmatrix} M & U_0 \\ N & V_0 \end{bmatrix} \begin{bmatrix} \tilde{V}_0 & -\tilde{U}_0 \\ -\tilde{N} & \tilde{M} \end{bmatrix}. \tag{6}$$

Exploiting this and the condition (5), it holds that $K = UV^{-1}$ stabilizes G_{22} if and only if

$$U = (U_0 - MQ) \text{ and } V = (V_0 - NQ) \text{ with } Q \in \mathcal{S}.$$

Similarly, K stabilizes G_{22} if and only if $K = (\tilde{V}_0 - Q\tilde{N})^{-1}(\tilde{U}_0 - Q\tilde{M})$ with $Q \in \mathcal{S}$. Together, these constitute the Youla-Kučera parametrizations of internally stabilizing controllers. Importantly, the coprime factors that appear in these are affine functions of the stable parameter Q. Moreover, using (6), an affine parametrization of the standard performance map (1) holds by direct substitution of either controller parametrization. Specifically,

$$H(G, K) = G_{11} + G_{12}K(I - G_{22}K)^{-1}G_{21}$$
$$= T_1 + T_2QT_3 \quad \text{with } Q \in \mathcal{S}, \quad (7)$$

where $T_1 = G_{11} + G_{12}U_0\tilde{M}G_{21}$, $T_2 = -G_{12}M$ and $T_3 = \tilde{M}G_{21}$. Clearly, $T_1 \in \mathcal{S}$ since this is the performance map when $Q = 0 \in \mathcal{S}$. By the assumption that G is stabilizable, it follows that T_2 and T_3 are also elements of $\mathcal{S}$; see Francis (1987, Chapter 4). The so-called Q-parametrization in (7) motivates the subsequent consideration of model-matching problems with respect to the standard measures of control system performance $\|\cdot\|_2$ and $\|\cdot\|_\infty$.

Model-Matching via Spectral Factorization

Bearing in mind the Q-parametrization (7), consider the following $\mathscr{H}_2$ model-matching problem,

where inf denotes greatest lower bound (infimum) and $T_i \in \mathcal{S}, i = 1, 2, 3$:

$$\inf_{Q \in \mathcal{S}} \|T_1 + T_2 Q T_3\|_2.$$

Assume that $T_2(s)$ and $T_3(s)$ have full column and row rank, respectively, for s on the extended imaginary axis. Also assume that T_1 is strictly proper, whereby Q must be strictly proper, and thus an element of $\mathcal{H} \subset \mathcal{S}$, for the performance index to be finite. Under this standard collec-

tion of assumptions, the infimum is achieved as shown below.

A minimizer of the convex functional $f := Q \in \mathcal{H} \mapsto \langle (T_1 + T_2 Q T_3), (T_1 + T_2 Q T_3) \rangle$ is a solution of the model matching problem. Given spectral factorizations $\Phi^\sim \Phi = T_2^\sim T_2$ and $\Lambda \Lambda^\sim = T_3 T_3^\sim$ (i.e., $\Phi, \Phi^{-1}, \Lambda, \Lambda^{-1} \in \mathcal{S}$), which exist by the assumptions on the problem data, let $R := \Phi Q \Lambda$ and $W := \Phi^{-\sim} T_2^\sim T_1 T_3^\sim \Lambda^{-\sim}$. Then for $Q \in \mathcal{H}$, which is equivalent to $R \in \mathcal{H}$ by the properties of spectral factors, it follows that

$$
\begin{aligned}
f(Q) &= \langle T_1, T_1 \rangle + \langle \Phi^{-\sim} T_2^\sim T_1 T_3^\sim \Lambda^{-\sim}, R \rangle + \langle R, \Phi^{-\sim} T_2^\sim T_1 T_3^\sim \Lambda^{-\sim} \rangle + \langle R, R \rangle \qquad (8) \\
&= \langle T_1, T_1 \rangle + \langle (\boldsymbol{\Pi}_-(W) + \boldsymbol{\Pi}_+(W) + R), (\boldsymbol{\Pi}_-(W) + \boldsymbol{\Pi}_+(W) + R) \rangle - \langle W, W \rangle \\
&= \langle T_1, T_1 \rangle - \langle \boldsymbol{\Pi}_+(W), \boldsymbol{\Pi}_+(W) \rangle + \langle (\boldsymbol{\Pi}_+(W) + R), (\boldsymbol{\Pi}_+(W) + R) \rangle, \qquad (9)
\end{aligned}
$$

where the second last equality holds by "completion-of-squares" and the last equality holds since $\langle \boldsymbol{\Pi}_+(W), \boldsymbol{\Pi}_-(W) \rangle = 0 = \langle R, \boldsymbol{\Pi}_-(W) \rangle$. From (9) it is apparent that

$$Q = -\Phi^{-1} \boldsymbol{\Pi}_+(\Phi^{-\sim} T_2^\sim T_1 T_3^\sim \Lambda^{-\sim}) \Lambda^{-1}$$

is a minimizer of f. As above, spectral factorization is a key component of the so-called Wiener-Hopf approach of Youla et al. (1976) and DeSantis et al. (1978).

Now consider the $\mathcal{H}_\infty$ model-matching problem

$$\inf_{Q \in \mathcal{S}} \|T_1 + T_2 Q T_3\|_\infty,$$

given $T_i \in \mathcal{S}, i = 1, 2, 3$. This is more challenging than the problem discussed above, where $\| \cdot \|_2$ is the performance index. While sufficient conditions are again available for the infimum to be achieved, computing a minimizer is generally difficult; see Francis and Doyle (1987) and Glover et al. (1991). As such, nearly optimal solutions are often sought by considering the relaxed problem of finding the set of $Q \in \mathcal{S}$ that satisfy $\|T_1 + T_2 Q T_3\|_\infty < \gamma$ for a value of $\gamma > 0$ greater than, but close to, the infimum.

With a view to highlighting the role of factorization methods and simplifying the presentation, suppose that T_2 is inner, which is possible without loss of generality via inner-outer factorization if $T_2(s)$ has full column rank for s on the extended imaginary axis. Furthermore, assume that $T_3 = I$. Following the approach of Francis (1987) and Green et al. (1990), let $X^\sim = \begin{bmatrix} X_1^\sim & X_2^\sim \end{bmatrix} := \begin{bmatrix} T_2 & I - T_2 T_2^\sim \end{bmatrix} \in \mathcal{B}$, so that $X^\sim X = I$ and $X T_2 = \begin{bmatrix} I \\ 0 \end{bmatrix}$. Observe that

$$
\begin{aligned}
\|T_1 + T_2 Q\|_\infty &= \|X(T_1 + T_2 Q)\|_\infty \\
&= \left\| \begin{bmatrix} T_2^\sim T_1 + Q \\ (I - T_2 T_2^\sim) T_1 \end{bmatrix} \right\|_\infty < \gamma
\end{aligned}
\qquad (10)
$$

if and only if

$$
\begin{aligned}
0 < \gamma^2 I &- T_1^\sim (I - T_2 T_2^\sim) T_1 \\
&- (T_2^\sim T_1 + Q)^\sim (T_2^\sim T_1 + Q) \qquad (11)
\end{aligned}
$$

on the extended imaginary axis. Note that (11) implies $0 < \gamma^2 I - T_1^\sim (I - T_2 T_2^\sim)^2 T_1$. Thus, it follows that there exists a $Q \in \mathcal{S}$ for which (10) holds if and only if the following are both satisfied: (a) there exists a spectral factorization

$\gamma^2 \Psi^\sim \Psi = \gamma^2 I - T_1^\sim (I - T_2 T_2^\sim)^2 T_1$; and (b) there exists an $\bar{R}(= Q\Psi^{-1}) \in \mathcal{S}$ such that $\|\bar{W} + \bar{R}\|_\infty < \gamma$, where $\bar{W} := T_2^\sim T_1 \Psi^{-1} \in \mathcal{B}$. The condition (b) is a well-known extension problem and a solution exists if and only if the induced norm of the Hankel operator with symbol $\bar{W}$ is less than γ, which is part of a result known as Nehari's theorem. In fact, (b) is equivalent to the existence of a spectral factor $\Upsilon, \Upsilon^{-1} \in \mathcal{S}$ with $\Upsilon_{11}^{-1} \in \mathcal{S}$ such that

$$\Upsilon^\sim \begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \Upsilon = \begin{bmatrix} I & \bar{W} \\ 0 & I \end{bmatrix}^\sim \begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \begin{bmatrix} I & \bar{W} \\ 0 & I \end{bmatrix}, \tag{12}$$

in which case $\|\bar{W} + \bar{R}\|_\infty \leq \gamma$ if and only if $\bar{R} = \bar{R}_1 \bar{R}_2^{-1}$ with $\begin{bmatrix} \bar{R}_1^T & \bar{R}_2^T \end{bmatrix} := \begin{bmatrix} \bar{S}^T & I \end{bmatrix} \Upsilon^{-T}$, $\bar{S} \in \mathcal{S}$ and $\|\bar{S}\|_\infty \leq \gamma$; see Ball and Ran (1987), Francis (1987), and Green et al. (1990) for details, including state-space constructions of the factors via Riccati equations. Noting that

$$\begin{bmatrix} T_2 & T_1 \\ 0 & I \end{bmatrix}^\sim \begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \begin{bmatrix} T_2 & T_1 \\ 0 & I \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & \Psi \end{bmatrix}^\sim \begin{bmatrix} I & \bar{W} \\ 0 & I \end{bmatrix}^\sim$$
$$\begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \begin{bmatrix} I & \bar{W} \\ 0 & I \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & \Psi \end{bmatrix},$$

it follows using (12) that there exists a $Q \in \mathcal{S}$ such that (10) holds if and only if there exists a spectral factor $\Omega, \Omega^{-1} \in \mathcal{S}$ with $\Omega_{11}^{-1} \in \mathcal{S}$ $\left(\Omega = \Upsilon \begin{bmatrix} I & 0 \\ 0 & \Psi \end{bmatrix}\right)$ that satisfies

$$\begin{bmatrix} T_2 & T_1 \\ 0 & I \end{bmatrix}^\sim \begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \begin{bmatrix} T_2 & T_1 \\ 0 & I \end{bmatrix} = \Omega^\sim \begin{bmatrix} I & 0 \\ 0 & -\gamma^2 I \end{bmatrix} \Omega, \tag{13}$$

in which case $\|T_1 + T_2 Q\|_\infty \leq \gamma$ if and only if $Q = Q_1 Q_2^{-1}$, where $\begin{bmatrix} Q_1^T & Q_2^T \end{bmatrix} := \begin{bmatrix} S^T & I \end{bmatrix} \Omega^{-T}$, $S \in \mathcal{S}$ and $\|S\|_\infty \leq \gamma$; see Green et al. (1990). So-called J-spectral factorizations of the kind in (12) and (13) also appear in the chain-scattering/conjugation approach of Kimura (1989, 1997) and the factorization approach of Ball et al. (1991), for example.

Summary

The preceding sections highlight the role of co-prime and spectral factorizations in formulating and solving model-matching problems that arise from standard $\mathcal{H}_2$ and $\mathcal{H}_\infty$ control problems. The transformation of standard control problems to model-matching problems hinges on an affine parametrization of internally stabilized performance maps. Beyond the problems considered here, this parametrization can be exploited to devise numerical algorithms for various other control problems in terms of convex mathematical programs.

Optimal Control with State Space Constraints

Heinz Schättler
Washington University, St. Louis, MO, USA

Abstract

Necessary and sufficient conditions for optimality in optimal control problems with state space constraints are reviewed with emphasis on geometric aspects.

Keywords

Problem Formulation and Terminology

Many practical problems in engineering or of scientific interest can be formulated in the framework of optimal control problems with state space constraints. Examples range from the space shuttle reentry problem in aeronautics (Bonnard et al. 2003) to the problem of minimizing the base transit time in bipolar transistors in electronics (Rinaldi and Schättler 2003).

An optimal control problem with state space constraints in Bolza form takes the following form: minimize a functional

$$J(u) = \int_{t_0}^{T} L(t, x(t), u(t)) dt + \Phi(T, x(T))$$

over all Lebesgue measurable functions $u : [t_0, T] \to U$ that take values in a control set $U \subset \mathbb{R}^m$, subject to the dynamics

$$\dot{x}(t) = F(t, x(t), u(t)), \qquad x(t_0) = x_0,$$

terminal constraints

$$\Psi(T, x(T)) = 0,$$

and state space constraints

$$h_\alpha(t, x(t)) \leq 0 \qquad \text{for } \alpha = 1, \ldots, r.$$

The focus of this contribution is on state space constraints, and, for simplicity, in this formulation, we have omitted mixed control state space constraints of the form $g_\beta(t, x, u) \leq 0$. States x lie in $\mathbb{R}^n$ and controls in $\mathbb{R}^m$; typically, the control set $U \subset \mathbb{R}^m$ is compact and convex, often a polyhedron. The time-varying vector field $F : \mathbb{R} \times \mathbb{R}^n \times U \to \mathbb{R}^n$ is continuously differentiable in (t, x), and the terminal constraint $N = \{(t, x) : \Psi(t, x) = 0\}$ is defined by continuously differentiable mappings $\psi_i : \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}^k$ with

the property that the gradients $\nabla \psi_i = (\frac{\partial \psi_i}{\partial t}, \frac{\partial \psi_i}{\partial x})$ (which we write as row vectors) are linearly independent on N. The terminal time T can be free or fixed; a fixed terminal time simply would be prescribed by one of the functions ψ_i. The state space constraints

$$M_\alpha = \{(t, x) : h_\alpha(t, x) = 0\}, \qquad \alpha = 1, \dots, r,$$

are defined by continuously differentiable time-varying vector fields $h_\alpha : \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}$, $(t, x) \mapsto h_\alpha(t, x)$, and we assume that the gradients ∇h_α do not vanish on M_α. In particular, each set M_α thus is an embedded submanifold of codimension 1 of $\mathbb{R}^{n+1}$. We denote by $h = (h_1, \dots, h_r)^T$ the time-varying vector field defining the state space constraints.

Terminology: *Admissible controls* are locally bounded Lebesgue measurable functions that take values in the control set, $u : [t_0, T] \to U$. Given any admissible control, the initial value problem $\dot{x}(t) = F(t, x(t), u(t))$, $x(t_0) = x_0$, has a unique solution defined on some maximal open interval of definition I. This solution is called the *trajectory* corresponding to the control u and the pair (x, u) is a *controlled trajectory*. An arc Γ of the graph of a trajectory defined over an open interval I for which none of the state space constraints is active is called an *interior arc*, and Γ is a *boundary arc* if at least one constraint is active on all of I. We call Γ an M_α-boundary arc over I if only the constraint $h_\alpha \leq 0$ is active on I. The times τ when interior arcs and boundary arcs meet are called *junction times* and the corresponding pairs $(\tau, x(\tau))$ *junction points*.

Despite the abundance and importance of practical problems that can be described as optimal control problems with state space constraints, for such problems the theory still lacks the coherence that the theory for problems without state space constraints has reached and there still exist significant gaps between the theories of necessary and sufficient conditions for optimality for optimal control problems with state space constraints. The theory of existence of optimal solutions differs little between optimal control problems with and without state space constraints, is well established, and will not be addressed here (e.g., see Cesari 1983 or the Filippov-Cesari theorem in Hartl et al. 1995).

Necessary Conditions for Optimality

First-order necessary conditions for optimality are given by the *Pontryagin maximum principle* (Pontryagin et al. 1962). The zero set of even a smooth (C^∞) function can be an arbitrary closed subset of the state space. As a result, in necessary conditions for optimality, the multipliers associated with the state space constraints a priori are only known to be nonnegative Radon measures (Ioffe and Tikhomirov 1979; Vinter 2000). Let $u_* : [t_0, T] \to U$ be an optimal control with corresponding trajectory x_* and, for simplicity of presentation, also assume that no state constraints are active at the terminal time so that the standard transversality conditions apply. Then it follows that there exist a constant $\lambda_0 \geq 0$, an absolutely continuous function η, which we write as row-vector, $\eta : [t_0, T] \to (\mathbb{R}^n)^*$, and nonnegative Radon measures $\mu_\alpha \in C^*([t_0, T]; \mathbb{R})$, $\alpha = 1, \dots, r$, with support in the sets $R_\alpha = \{t \in [t_0, T] : h_\alpha(t, x_*(t)) = 0\}$, which do not all vanish simultaneously, i.e.,

$$\lambda_0 + \|\eta\|_\infty + \sum_{\alpha=1}^r \mu_\alpha([t_0, T]) > 0,$$

such that with

$$\lambda(t) = \eta(t) - \sum_{\alpha=1}^r \int_{[t_0, t)} \frac{\partial h_\alpha}{\partial x}(s, x_*(s)) d\mu_\alpha(s),$$

and

$$H = H(t, \lambda_0, \lambda, x, u) = \lambda_0 L(t, x, u) + \lambda F(t, x, u)$$

the following conditions hold:

(a) The adjoint equation holds in the form

$$\dot{\eta}(t) = -\frac{\partial H}{\partial x}(t, \lambda_0, \lambda(t), x_*(t), u_*(t))$$

$$= -\lambda_0 \frac{\partial L}{\partial x}(t, x_*(t), u_*(t))$$

$$- \lambda(t) \frac{\partial F}{\partial x}(t, x_*(t), u_*(t)),$$

and there exists a row-vector $\mu \in (\mathbb{R}^k)^*$ such that

$$\lambda(T) = \lambda_0 \frac{\partial \Phi}{\partial x}(T, x_*(T)) + \mu \frac{\partial \Psi}{\partial x}(T, x_*(T))$$

and

$$0 = H(T, \lambda_0, \lambda(T), x_*(T), u_*(T))$$

$$+ \lambda_0 \frac{\partial \Phi}{\partial t}(T, x_*(T)) + \mu \frac{\partial \Psi}{\partial t}(T, x_*(T)).$$

(b) The optimal control minimizes the Hamiltonian over the control set U along $(\lambda(t), x_*(t))$:

$$H(t, \lambda_0, \lambda(t), x_*(t), u_*(t))$$

$$= \min_{v \in U} H(t, \lambda_0, \lambda(t), x_*(t), v).$$

Furthermore,

$$H(t, \lambda_0, \lambda(t), x_*(t), u_*(t))$$

$$= H(T, \lambda_0, \lambda(t), x_*(t), u_*(t))$$

$$- \int_{[t,T]} \frac{\partial H}{\partial t}(s, \lambda_0, \lambda(s), x_*(s), u_*(s)) ds$$

$$+ \sum_{\alpha=1}^{r} \int_{[t,T]} \frac{\partial h_\alpha}{\partial t}(s, x_*(s)) d\mu_\alpha(s)$$

Controlled trajectories (x, u) for which there exist multipliers such that these conditions are satisfied are called *extremals*. In general, it cannot be excluded that λ_0 vanishes and extremals with $\lambda_0 = 0$ are called *abnormal*, while those with $\lambda_0 > 0$ are called *normal*. In this case, the multiplier can be normalized, $\lambda_0 = 1$.

Special Case: A Mayer Problem for Single-Input Control Linear Systems

Under the general assumptions formulated above, the sets $R_\alpha \subset [t_0, T]$ when a particular constraint is active can be arbitrarily complicated.

But in many practical applications, state constraints have strong geometric properties – often they are embedded submanifolds – and it is possible to strengthen these necessary conditions for optimality in the sense of specifying the measures further. We formulate the conditions for a particular case of common interest.

We consider an optimal control problem in *Mayer form* (i.e., $L \equiv 0$) for a single-input control linear system with dynamics

$$\dot{x} = F(t, x, u) = f(t, x) + u g(t, x)$$

and the control set U a compact interval, $U = [a, b]$. Adjoining time as extra state variable, $\dot{t} \equiv 1$, and defining

$$F_0(t, x) = \begin{pmatrix} 1 \\ f(t, x) \end{pmatrix} \text{ and } G(t, x) = \begin{pmatrix} 0 \\ g(t, x) \end{pmatrix},$$

for a continuously differentiable function $k : \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}^n$, the expressions

$$\mathcal{L}_{F_0} k : \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}^n,$$

$$(t, x) \mapsto (\mathcal{L}_{F_0} k)(t, x)$$

$$= \frac{\partial k}{\partial t}(t, x) + \frac{\partial k}{\partial x}(t, x) f(t, x)$$

and

$$\mathcal{L}_G k : \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}^n,$$

$$(t, x) \mapsto (\mathcal{L}_G k)(t, x) = \frac{\partial k}{\partial x}(t, x) g(t, x)$$

represent the Lie (or directional) derivatives of the function k along the vector fields F_0 and G, respectively. In terms of this notation, the derivative of the function h_α (defining the manifold M_α) along trajectories of the system is given by

$$\dot{h}_\alpha(t, x(t)) = \frac{d}{dt} h_\alpha(t, x(t))$$

$$= \mathcal{L}_{F_0} h_\alpha(t, x(t)) + u(t) \mathcal{L}_G h_\alpha(t, x(t)).$$

If the function $\mathcal{L}_G h_\alpha$ does not vanish at a point $(\tilde{t}, \tilde{x}) \in M_\alpha$, then there exists a neighborhood V of $(\tilde{t}, \tilde{x})$ such that there exists a unique

control $u_\alpha = u_\alpha(t, x)$ which solves the equation $\dot{h}_\alpha(t, x) = 0$ on V and u_α is given in feedback form as

$$u_\alpha(t, x) = -\frac{\mathcal{L}_{F_0} h_\alpha(t, x)}{\mathcal{L}_G h_\alpha(t, x)}.$$

The manifold M_α is said to be *control invariant* of *relative degree* 1 if the Lie derivative of h_α with respect to G, $\mathcal{L}_G h_\alpha$, does not vanish anywhere on M_α and if the function $u_\alpha(t, x)$ is admissible, i.e., takes values in the control set $[a, b]$.

Thus, for a control-invariant submanifold of relative degree 1, the control that keeps the manifold invariant is unique, and the corresponding dynamics induce a unique flow on the constraint. This assumption corresponds to the least degenerate, i.e., in some sense most generic or common, scenario and is satisfied for many practical problems.

Suppose the reference extremal is normal and let Γ_α be an M_α-boundary arc defined over an open interval I with corresponding boundary control u_α that takes values in the interior of the control set along Γ_α. Then the Radon measure μ_α is absolutely continuous with respect to Lebesgue measure on I with continuous and nonnegative Radon-Nikodym derivative $\nu_\alpha(t)$ given by

$$\nu_\alpha(t) = \frac{\lambda(t)\left(\frac{\partial g}{\partial t}(t, x_*(t)) + [f, g](t, x_*(t))\right)}{\mathcal{L}_G h_\alpha(t, x_*(t))}$$

where $[f, g]$ denotes the Lie bracket of the time-varying vector fields f and g in the variable x,

$$[f, g](t, x) = \frac{\partial g}{\partial x}(t, x) f(t, x) - \frac{\partial f}{\partial x}(t, x) g(t, x).$$

In particular, in this case, the adjoint equation can be expressed in the more common form

$$\dot{\lambda}(t) = -\lambda(t)\frac{\partial F}{\partial x}(t, x_*, u_*) - \nu_\alpha(t)\frac{\partial h_\alpha}{\partial x}(t, x_*),$$

with all partial derivatives evaluated along the reference trajectory. Furthermore, the multiplier λ remains continuous at entry or exit if the controlled trajectory (x_*, u_*) meets the constraint

M_α transversally (e.g., see Schättler 2006). This follows from the following characterization of transversal connections between interior and boundary arcs due to Maurer (1977): if τ is an entry or exit junction time between an interior arc and an M_α-boundary arc for which the reference control u_* has a limit at τ along the interior arc, then the interior arc is transversal to M_α at entry or exit if and only if the control u_* is discontinuous at τ.

Informal Formulation of Necessary Conditions

In order to ensure the practicality of necessary conditions for optimality, it is essential that besides atomistic structures at junctions that lead to computable jumps in the multipliers, the Radon measures μ_α have no singular parts with respect to Lebesgue measure. If it is *assumed* a priori that optimal controlled trajectories are finite concatenations of interior and boundary arcs, and if the constraint sets have a reasonably regular structure (embedded submanifolds and transversal intersections thereof) and satisfy a rather technical *constraint qualification* (see Hartl et al. 1995) that guarantees that the restrictions of the system to active constraints have solutions, then it is possible to specify the above necessary conditions further and formulate more user friendly versions for the determination of the multipliers. Such formulations have become the standard for numerical computations, but they still have not always been established rigorously and somewhat carry the stigma of a heuristic nature. Nevertheless, it is often this more concrete set of conditions that allow to solve problems numerically and analytically. If then, in conjunction with sufficient conditions for optimality, it is possible to verify the optimality of the computed extremal solutions, this generates a satisfactory theoretical procedure. Such conditions, following Hartl et al. (1995), generally are referred to as the "informal theorem".

Suppose (x_*, u_*) is a normal extremal controlled trajectory defined over the interval $[t_0, T]$ with the property that the graph of x_* is a finite concatenation of interior and boundary arcs with junction times τ_i, $i = 1, \ldots, k$, $t_0 = \tau_0 < \tau_1 <$

$\ldots < \tau_k < \tau_{k+1} = T$. Under an appropriate constraint qualification, there exist a multiplier λ, $\lambda : [t_0, T] \to (\mathbb{R}^n)^*$, which is absolutely continuous on each subinterval $[\tau_i, \tau_{i+1}]$; multipliers $\nu_\alpha, \nu_\alpha : [t_0, T] \to (\mathbb{R}^n)^*$, which are continuous on each interval $[\tau_i, \tau_{i+1}]$; a vector $\mu \in (\mathbb{R}^k)^*$; and vectors $\eta(\tau_i) \in (\mathbb{R}^r)^*$, $i = 1, \ldots, k$, with nonnegative entries such that:

(a) (adjoint equation) On each interval (τ_i, τ_{i+1}), $i = 0, \ldots, r$, λ satisfies the adjoint equation in the form

$$\dot{\lambda}(t) = -\frac{\partial L}{\partial x}(t, x_*(t), u_*(t))$$
$$-\lambda(t)\frac{\partial F}{\partial x}(t, x_*(t), u_*(t))$$
$$-\sum_{\alpha=1}^{r} \nu_\alpha(t)\frac{\partial h_\alpha}{\partial x}(t, x_*),$$

with $\nu_\alpha(t) = 0$ if the constraint M_α is not active at time t. Assuming that no state space constraint is active at the terminal time, the value of the multiplier λ at the terminal time is given by the transversality condition

$$\lambda(T) = \frac{\partial \Phi}{\partial x}(T, x_*(T)) + \mu\frac{\partial \Psi}{\partial x}(T, x_*(T)).$$

At any junction time τ_i between an interior arc and a boundary arc, the multiplier λ may be discontinuous satisfying a jump condition of the form

$$\lambda(\tau_i-) = \lambda(\tau_i+) + \eta(\tau_i)\frac{\partial h}{\partial x}(\tau_i, x_*(\tau_i))$$

and the complementary slackness condition

$$\eta(\tau_i)\frac{\partial h}{\partial x}(\tau_i, x_*(\tau_i)) = 0$$

holds.

(b) The optimal control minimizes the Hamiltonian over the control set U along $(\lambda(t), x_*(t))$:

$$H(t, \lambda(t), x_*(t), u_*(t))$$
$$= \min_{v \in U} H(t, \lambda(t), x_*(t), v)$$

and at the junction times τ_i we have that

$$H(\tau_i, \lambda(\tau_i-), x_*(\tau_i), u_*(\tau_i-))$$
$$= H(\tau_i, \lambda(\tau_i+), x_*(\tau_i), u_*(\tau_i+))$$
$$-\eta(\tau_i)\frac{\partial h}{\partial t}(\tau_i, x_*(\tau_i)).$$

Sufficient Conditions for Optimality

The literature on sufficient conditions for optimality for optimal control problems with state space constraints is limited. The value function for an optimal control problem at a point (t, x) in the extended state space, $V = V(t, x)$, is defined as the infimum over all admissible controls u for which the corresponding trajectory starts at the point x at time t and satisfies all the constraints of the problem,

$$V(t, x) = \inf_{u \in \mathcal{U}} J(u).$$

Any sufficiency theory for optimal control problems, one way or another, deals with the solution of the corresponding Hamilton-Jacobi-Bellman (HJB) equation:

$$\frac{\partial V}{\partial t}(t, x) + \min_{u \in U}\left\{\frac{\partial V}{\partial x}(t, x)F(t, x, u)\right.$$
$$\left. + L(t, x, u)\right\} \equiv 0,$$
$$V(T, x) = \Phi(T, x) \text{ whenever } \Psi(T, x) = 0.$$

Value functions for optimal control problems rarely are differentiable everywhere, but generally have singularities along lower-dimensional submanifolds. Nevertheless, under some technical assumptions and with proper interpretations of the derivatives, this equation describes the evolution of the value function of an optimal control problem and, if an appropriate solution can be constructed, indeed solves the optimal control problem.

There exists a broad theory of viscosity solutions to the HJB equation (e.g., Fleming and

Soner 2005; Bardi and Capuzzo-Dolcetta 2008) that is also applicable to problems with state space constraints (Soner 1986) and, under varying technical assumptions, characterizes the value function V as the unique viscosity solution to the HJB equation. This has led to the development of algorithms that can be used to compute numerical solutions.

A more classical and more geometric approach to solving the HJB equation is based on the method of characteristics and goes back to the work of Boltyansky on a regular synthesis for optimal control problems without state space constraints (Boltyanskii 1966). This work follows classical ideas of fields of extremals from the calculus of variations and imposes technical conditions that allow to handle the singularities that arise in the value functions (e.g., see, Schättler and Ledzewicz 2012). Stalford's results in Stalford (1971) follow this approach for problems with state space constraints, but a broadly applicable theory of

regular synthesis, as it was developed by Piccoli and Sussmann in (2000) for problems without state space constraints, does not yet exist for problems with state space constraints. Results that embed a controlled reference extremal into a local field of extremals have been given by Bonnard et al. (2003) or Schättler (2006), and these constructions show the applicability of the concepts of a regular synthesis to problems with state space constraints as well.

Examples of Local Embeddings of Boundary Arcs

We illustrate the typical, i.e., in some sense most common, generic structures of local embeddings of boundary arcs in Figs. 1 and 2. The state constraint M_α is a control-invariant submanifold of relative degree 1 and represented by a horizontal line as it arises when limits on the size of a particular state are imposed. Figure 1 shows the typical entry-boundary-exit concatenations of an interior arc followed by a boundary arc and

Optimal Control with State Space Constraints, Fig. 1 A typical local synthesis around a boundary arc when no terminal constraints are present
Optimal Control with State Space Constraints, Fig. 2 A typical local synthesis around a boundary arc when terminal constraints are present
another interior arc. The local embedding of the boundary arc differs substantially from classical local imbeddings for unconstrained problems in the sense that this field necessarily contains small pieces of trajectories which, when propagated backward, are not close to the reference trajectory. This, however, does not affect the memoryless properties required for a synthesis forward in time, and strong local optimality of the reference trajectory can be proven combining synthesis type arguments with homotopy type approximations of the synthesis (Schättler 2006). The one trajectory marked as black line in Fig. 1 corresponds to an optimal trajectory that meets the constraint only at the junction point and immediately bounces back into the interior. Such a trajectory arises as the limit when the concatenation structure of optimal controlled trajectories changes from interior-boundary-interior arcs to trajectories that do not meet the constraint. These structures are one of the extra sources for singularities in the value function that come up in optimal control problems with state space constraints. Switching surfaces for the interior arcs, as one is also shown in this figure, do not cause such a loss of differentiability if they are crossed transversally be the extremal trajectories of the field.

Figure 2 depicts the structure of an optimal synthesis for a problem from electronics, the problem of minimizing the base transit time of bipolar homogeneous transistors. The electrical field that determines the transit time is controlled by tailoring a distribution of dopants in the base region, and this dopant profile becomes an important design parameter determining the speed of the device. But due to physical and engineering limitations, the variables describing the dopants need to be limited, and thus this becomes an optimal control problem with state space constraints represented by hard limits on the variables. The constraints here are control invariant of relative degree 1. Optimal solutions, in the presence of initial and terminal constraints, have both portions along the upper and lower control limits of the constrained variable and typically proceed from the upper to the lower values along an optimal singular control (which takes values in

the interior of the control set) in the interior of the admissible domain, possibly with saturation if the control limits are reached.

Optimal Deployment and Spatial Coverage

Sonia Martínez

Department of Mechanical and Aerospace Engineering, University of California, La Jolla, San Diego, CA, USA

Abstract

Optimal deployment refers to the problem of how to allocate a finite number of resources over a spatial domain to maximize a performance metric that encodes certain quality of service. Depending on the deployment environment, the type of resource, and the metric used, the solutions to this problem can greatly vary.

Keywords

Coverage control algorithms; Facility location problems

Introduction

The problem of deciding what are optimal geographic locations to place a set of facilities has a long history and is the main subject in operations research and management science; see Drezner (1995). A facility can be broadly understood as a service such as a school; a hospital; an airport; an emergency service, such as a fire station; or, more generally, routes of a vehicle, from buses to aircraft, an autonomous vehicle, or a mobile sensor.

The specific formulation of facility location problems depends very much on the particular underlying application. A distinguishing feature is that all involve strategic planning, accounting for the long-term impact on the facility operating cost and their fast response to the demand. Thus, these problems lead to constrained optimization formulations which are typically very hard to solve optimally. The computational complexity of such problems, which, even in their most basic formulations, typically lead to NP-hard problems, has made their solution largely intractable until the advent of high-speed computing.

Locational optimization techniques have also been employed to solve optimal estimation problems by static sensor networks, mesh and grid optimization design, clustering analysis, data compression, and statistical pattern recognition; see Du et al. (1999). However, these solutions typically require centralized computations and availability of information at all times.

When the facilities are multiple vehicles or mobile sensors, the underlying dynamics may require additional changes and further analysis that guarantee the overall system stability. In what follows, we review a particular coverage control problem formulation in terms of the so-called expected-value multicenter functions that makes the analysis tractable leading to robust, distributed algorithm implementations employing computational geometric objects such as Voronoi partitions.

Basic Ingredients from Computational Geometry

In order to formulate a basic optimal deployment problem and algorithm, we require of several notions from computational geometry; see Bullo et al. (2009) for more information.

Let S be a measurable set of $\mathbb{R}^m$, for $m \in \mathbb{N}$, consider a distance function d on $\mathbb{R}^m$, and let $P = \{p_1, \ldots, p_n\}$ be n distinct points of S, corresponding to *locations* of certain facilities. The *Voronoi partition* of S generated by P and associated with d is given by $\mathcal{V}(P) = \{V_1(P), \ldots, V_n(P)\}$, where

$$V_i(P) = \{q \in S \mid d(p_i, q) \leq d(p_j, q),$$
$$j \in P \setminus \{i\}\}, \quad i \in \{1, \ldots, n\}.$$

Given $r \in \mathbb{R}_{>0}$, denote by $\overline{B}(p_i, r)$ the closed ball of center p_i and radius r. The *r-limited Voronoi partition* of S generated by P and associated with d is the Voronoi partition of the set $S \cap \cup_{i=1}^{n} \overline{B}(p_i, r)$, denoted as $\mathcal{V}_r(P) = \{V_{1,r}(P), \ldots V_{n,r}(P)\}$.

Let $\phi : S \rightarrow \mathbb{R}_{\geq 0}$ be a measurable *density* function on S. The *area* and the *centroid* (or *center of mass*) of $W \subseteq S$ with respect to ϕ are the values

$$A_\phi(W) = \int_W \phi(q) dq,$$

$$\mathrm{CM}_\phi(W) = \frac{1}{A_\phi(W)} \int_W q \phi(q) dq.$$

We say that the set of distinct points P in S is a *centroidal Voronoi configuration* (resp., a *r-limited centroidal Voronoi configuration*) if each p_i is at the centroid of its own Voronoi cell. That is, $p_i = \mathrm{CM}_\phi(V_i(P))$, $i \in \{1, \ldots, n\}$ (resp., $p_i = \mathrm{CM}_\phi(V_{i,r}(P))$, and $i \in \{1, \ldots, n\}$). Voronoi partitions and centroidal Voronoi configurations help assess the distribution of locations in a spatial domain as we establish below.

A Voronoi partition induces a natural *proximity graph*, called the *Delaunay graph*, over the set of points P. We recall that a *graph G* is a pair $G = (V, E)$ where V is a set of n vertices and E is a set of ordered pair of *vertices*, $E \subset V \times V$, called *edge set*. A *proximity graph* is a graph function defined on the set S, which assigns a set of distinct points $P \subset S$ to a graph $G(P) = (P, E(P))$, where $E(P)$ is a function of the relative locations of the point set. Example graphs include the following:

1. The *r-disk graph*, $\mathcal{G}_{\mathrm{disk},r}$, for $r \in \mathbb{R}_{>0}$. Here, $(p_i, p_j) \in E_{\mathrm{disk},r}(P)$ if $d(p_i, p_j) \leq r$.
2. The *Delaunay graph*, $\mathcal{G}_{\mathrm{D}}$. We have $(p_i, p_j) \in E_{\mathrm{D}}(P)$ if $V_i(P) \cap V_j(P) \neq \emptyset$.
3. The *r-limited Delaunay graph*, $\mathcal{G}_{\mathrm{LD},r}$, for $r \in \mathbb{R}_{>0}$. Here, $(p_i, p_j) \in E_{\mathrm{LD},r}(P)$ if $V_{i,r}(P) \cap V_{i,r}(P) \neq \emptyset$.

Expected-Value Multicenter Functions

Facility location problems consist of spatially allocating a number of sites to provide certain quality of service. Problems of this class are formulated in terms of multicenter functions and, in particular, expected-value multicenter functions.

To define these, consider $\phi : S \rightarrow \mathbb{R}_{\geq 0}$ a density function over a bounded measurable set $S \subset \mathbb{R}^m$. One can regard ϕ as a function measuring the probability that some event takes place over the environment. The larger the value of $\phi(q)$, the more important the location q will have. We refer to a nonincreasing and piecewise continuously differentiable function $f : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}$, possibly with finite jump discontinuities, as a *performance function*.

Performance functions describe the utility of placing a node at a certain distance from a location in the environment. The smaller the distance, the larger the value of f, that is, the better the performance. For instance, in sensing problems, performance functions can encode the signal-to-noise ratio between a source with an unknown location and a sensor attempting to locate it. Without loss of generality, it can be assumed that $f(0) = 0$.

An *expected-value multicenter function* models the expected value of the coverage over any point in S provided by a set of points $p_1, \ldots, p_n$. Formally,

$$\mathcal{H}(p_1, \ldots, p_n) = \int_S \max_{i \in \{1, \ldots, n\}} f(\|q - p_i\|_2) \phi(q) dq, \tag{1}$$

where $\| \cdot \|_2$ denotes the 2-norm of $\mathbb{R}^m$. This definition can be understood as follows: consider the best coverage of $q \in S$ among those provided by each of the nodes $p_1, \ldots, p_n$, which corresponds to the value $\max_{i \in \{1, \ldots, n\}} f(\|q - p_i\|_2)$. Then, modulate the performance by the importance $\phi(q)$ of the location q. Finally, the infinitesimal sum of this quantity over the environment S gives rise to $\mathcal{H}(p_1, \ldots, p_n)$ as a measure of the overall coverage provided by $p_1, \ldots, p_n$.

From here, we can formulate the following geometric optimization problem, known

as the *continuous p-median problem*, see Drezner (1995):

$$\max_{\{p_1,\dots,p_n\}\subset S} \mathcal{H}(p_1,\dots,p_n). \qquad (2)$$

The expected-value multicenter function can be alternatively described in terms of the Voronoi partition of S generated by $P = \{p_1,\dots,p_n\}$. Let us define the set

$$\mathcal{C} = \big\{(p_1,\dots,p_n) \in (\mathbb{R}^m)^n \mid p_i = p_j$$
$$\text{for some } i \neq j\big\},$$

consisting of tuples of n points, where some of them are repeated. Then, for $(p_1,\dots,p_n) \in S^n \setminus \mathcal{C}$, one has

$$\mathcal{H}(p_1,\dots,p_n) = \sum_{i=1}^{n} \int_{V_i(P)} f(\|q - p_i\|_2)\phi(q)dq. \qquad (3)$$

This expression of $\mathcal{H}$ is appealing because it clearly shows the result of the overall coverage of the environment as the aggregate contribution of all individual nodes. If $(p_1,\dots,p_n) \in \mathcal{C}$, then a similar decomposition of $\mathcal{H}$ can be written in terms of the distinct points $P = \{p_1,\dots,p_n\}$.

Inspired by (3), a more general version of the expected-value multicenter function is given next. Given $(p_1,\dots,p_n) \in S^n$ and a partition $\{W_1,\dots,W_n\}$ of S, let

$$\mathcal{H}(p_1,\dots,p_n, W_1,\dots,W_n)$$
$$= \sum_{i=1}^{n} \int_{W_i} f(\|q - p_i\|_2)\phi(q)dq. \qquad (4)$$

For all $(p_1,\dots,p_n) \in S^n \setminus \mathcal{C}$, we have that $\mathcal{H}(p_1,\dots,p_n) = \mathcal{H}(p_1,\dots,p_n, V_1(P),\dots,V_n(P))$. With respect to, e.g., sensor networks, this function evaluates the performance associated with an assignment of the sensors' locations at $(p_1,\dots,p_n)$ and a region assignment $(W_1,\dots,W_n)$.

Moreover, one can establish that the Voronoi partition (Du et al. 1999) $\mathcal{V}(P)$ is optimal for $\mathcal{H}$ among all partitions of S. That is, let $P =$

$\{p_1,\dots,p_n\} \in S$. For any performance function f and for any partition $\{W_1,\dots,W_n\}$ of S,

$$\mathcal{H}(p_1,\dots,p_n, V_1(P),\dots,V_n(P)) \geq$$
$$\mathcal{H}(p_1,\dots,p_n, W_1,\dots,W_n),$$

with a strict inequality if any set in $\{W_1,\dots,W_n\}$ differs from the corresponding set in $\{V_1(P),\dots,V_n(P)\}$ by a set of positive measure.

Next, we characterize the smoothness of the expected-value multicenter function (Cortés et al. 2005). Before stating the precise properties, let us introduce some useful notation. For a performance function f, let discont(f) denote the (finite) set of points where f is discontinuous. For each $a \in \text{discont}(f)$, define the limiting values from the left and from the right, respectively, as

$$f_-(a) = \lim_{x\to a^-} f(x), \qquad f_+(a) = \lim_{x\to a^+} f(x).$$

Recall that the line integral of a function $g : \mathbb{R}^2 \to \mathbb{R}$ over a curve C parameterized by a continuous and piecewise continuously differentiable map $\gamma : [0,1] \to \mathbb{R}^2$ is defined as follows:

$$\int_C g = \int_C g(\gamma)d\gamma := \int_0^1 g(\gamma(t))\,\|\dot{\gamma}(t)\|_2\,dt,$$

and is independent of the selected parameterization.

Now, given a set $S \subset \mathbb{R}^m$ that is bounded and measurable, a density $\phi : S \to \mathbb{R}_{\geq 0}$, and a performance function $f : \mathbb{R} \to_{\geq 0} \mathbb{R}$, the expected-value multicenter function $\mathcal{H} : S^n \to \mathbb{R}$ is globally Lipschitz (Given $S \subset \mathbb{R}^h$, a function $f : S \to \mathbb{R}^k$ is globally Lipschitz if there exists $K \in \mathbb{R}_{>0}$ such that $\|f(x) - f(y)\|_2 \leq K\|x - y\|_2$ for all $x, y \in S$.) on S^n; and continuously differentiable on $S^n \setminus \mathcal{C}$, where for $i \in \{1,\dots,n\}$

$$\frac{\partial\mathcal{H}}{\partial p_i}(P) = \int_{V_i(P)} \frac{\partial}{\partial p_i} f(\|q - p_i\|_2)\phi(q)dq$$
$$+ \sum_{a\in\text{discont}(f)} (f_-(a) - f_+(a))$$
$$\int_{V_i(P)\cap\partial\overline{B}(p_i,a)} \mathrm{n}_{\text{out}}(q)\phi(q)dq, \qquad (5)$$

where n_{out} is the outward normal vector to $\overline{B}(p_i, a)$.

Different performance functions lead to different expected-value multicenter functions. Let us examine some important cases.

Distortion Problem

Consider the performance function $f(x) = -x^2$. Then, on $S^n \setminus \mathcal{C}$, the expected-value multicenter function takes the form

$$\mathcal{H}_{\text{distor}}(p_1, \ldots, p_n) = -\sum_{i=1}^{n} \int_{V_i(P)} \|q - p_i\|_2^2 \phi(q) dq.$$

In signal compression $-\mathcal{H}_{\text{distor}}$ is referred to as the *distortion function* and is relevant in many disciplines where including vector quantization, signal compression, and numerical integration; see Gray and Neuhoff (1998) and Du et al. (1999). Here, distortion refers to the average deformation (weighted by the density ϕ) caused by reproducing $q \in S$ with the location p_i in $P = \{p_1, \ldots, p_n\}$ such that $q \in V_i(P)$. By means of the Parallel Axis Theorem (see Hibbeler 2006), it is possible to express $\mathcal{H}_{\text{distor}}$ as a sum

$$\mathcal{H}_{\text{distor}}(p_1, \ldots, p_n, W_1, \ldots, W_n)$$
$$= \sum_{i=1}^{n} -J_\phi(W_i, \text{CM}_\phi(W_i))$$
$$- A_\phi(W_i) \|p_i - \text{CM}_\phi(W_i)\|_2^2, \quad (6)$$

where $J_\phi(W, p) = \int_W \|q - p\|^2 \phi(q) dq$ is the so-called moment of inertia of the region W about p with respect to ϕ. In this way, the terms $J_\phi(W_i, \text{CM}_\phi(W_i))$ only depend on the partition of S, whereas the second terms multiplied by $A_\phi(W_i)$ include the particular location of the points. As a consequence of this observation, the optimality of the centroid locations for $\mathcal{H}_{\text{distor}}$ follows Bullo et al. (2009). More precisely, let $\{W_1, \ldots, W_n\}$ be a partition of S. Then, for any set points $P = \{p_1, \ldots, p_n\}$ in S,

$$\mathcal{H}_{\text{distor}}(\text{CM}_\phi(W_1), \ldots, \text{CM}_\phi(W_n), W_1, \ldots, W_n)$$
$$\geq \mathcal{H}_{\text{distor}}(p_1, \ldots, p_n, W_1, \ldots, W_n),$$

and the inequality is strict if there exists $i \in \{1, \ldots, n\}$ for which W_i has nonvanishing area and $p_i \neq \text{CM}_\phi(W_i)$. In other words, the centroid locations $\text{CM}_\phi(W_1), \ldots, \text{CM}_\phi(W_n)$ are optimal for $\mathcal{H}_{\text{distor}}$ among all configurations in S.

Note that when $n = 1$, the node location that optimizes $p \mapsto \mathcal{H}_{\text{distor}}(p)$ is the centroid of the set S, denoted by $\text{CM}_\phi(S)$.

Recall that the gradient of $\mathcal{H}_{\text{distor}}$ on $S^n \setminus \mathcal{C}$ takes the form,

$$\frac{\partial \mathcal{H}_{\text{distor}}}{\partial p_i}(P) = 2A_\phi(V_i(P))(\text{CM}_\phi(V_i(P)) - p_i),$$
$$i \in \{1, \ldots, n\},$$

that is, the ith component of the gradient points in the direction of the vector going from p_i to the centroid of its Voronoi cell. The critical points of $\mathcal{H}_{\text{distor}}$ are therefore the set of centroidal Voronoi configurations in S. This is a natural generalization of the result for the case $n = 1$, where the optimal node location is the centroid $\text{CM}_\phi(S)$.

Area Problem

For $r \in \mathbb{R}_{>0}$, consider the performance function $f(x) = 1_{[0,r]}(x)$, that is, the indicator function of the closed interval $[0, r]$. Then, the expected-value multicenter function becomes

$$\mathcal{H}_{\text{area},r}(p_1, \ldots, p_n) = \sum_{i=1}^{n} A_\phi(V_i(P) \cap \overline{B}(p_i, r))$$
$$= A_\phi(\cup_{i=1}^{n} \overline{B}(p_i, r)),$$

which corresponds to the area, measured according to ϕ, covered by the union of the n balls $\overline{B}(p_1, r), \ldots, \overline{B}(p_n, r)$.

Let us see how the computation of the partial derivatives of $\mathcal{H}_{\text{area},r}$ specializes in this case. Here, the performance function is differentiable everywhere except at a single discontinuity, and its derivative is identically zero. Therefore, the first term in (5) vanishes. The gradient of $\mathcal{H}_{\text{area},r}$

on $S^n \setminus \mathcal{C}$ then takes the form, for each $i \in \{1, \ldots, n\}$,

$$\frac{\partial \mathcal{H}_{\text{area},r}}{\partial p_i}(P) = \int_{V_i(P) \cap \partial \overline{B}(p_i, r)} \mathrm{n}_{\text{out}}(q)\phi(q)dq,$$

where n_{out} is the outward normal vector to $\overline{B}(p_i, r)$. The critical points of $\mathcal{H}_{\text{area},r}$ correspond to configurations with the property that each p_i is a local maximum for the area of $V_{i,r}(P) = V_i(P) \cap \overline{B}(p_i, r)$ at fixed $V_i(P)$. We refer to these configurations as *r-limited area-centered* Voronoi configurations.

Optimal Deployment Algorithms

Once a set of optimal deployment configurations have been characterized, the next step is to devise a distributed algorithm that allows a group of mobile robots to converge to such configurations. Gradient algorithms are the first of the options that should be explored.

For the expected-value multicenter functions, robots whose dynamics can be described by first-order integrator dynamics and which can communicate at predetermined *communication rounds* of a fixed time schedule, these laws present a similar structure, loosely described as follows:

> [*Informal description*] In each communication round, each robot performs the following tasks: (i) it transmits its position and receives its neighbors' positions; (ii) it computes a notion of the geometric center of its own cell, determined according to some notion of partition of the environment. (iii) Between communication rounds, each robot moves toward this center.

The notions of geometric center and of partition of the environment differ depending on what is the type of expected-value multicenter function used. In the *Voronoi-center deployment algorithm*, the geometric center just reduces to $\mathrm{CM}_\phi(V_i)$. In the *limited-Voronoi-normal* deployment problem in (ii), each agent computes the direction of $v = \frac{\partial \mathcal{H}_{\text{area},r}}{\partial p_i}$ for some r and (iii) moves for a maximum step size in this direction to ensure the area function will be decreased.

The Voronoi-center deployment algorithm achieves convergence of a set of nodes to a centroidal Voronoi configuration, thus maximizing the expected-value multicenter function $\mathcal{H}_{\text{distor}}$. The algorithm is distributed over the proximity graph $\mathcal{G}_D$, as the computation of the centroids requires information in $\mathcal{N}_{\mathcal{G}_D}(p_i)$, for each $i \in \{1, \ldots, n\}$. Additional properties of this algorithm are that the algorithm is adaptive to agent departures or arrivals and amenable to asynchronous implementations.

On the other hand, the limited-Voronoi-normal deployment algorithm achieves convergence to a set that locally maximizes the area covered by the set of sensing balls. The algorithm is distributed in the sense that agents only need to know information from neighbors in the proximity graph $\mathcal{G}_{2r}$ or, more precisely, $\mathcal{G}_{\text{LD},r}$. Thus, it can be implemented by agents that employ range-limited interactions. It enjoys similar robustness properties as the Voronoi-center deployment algorithm.

Simulation Results

We show evolutions of the Voronoi-centroid deployment algorithm in Fig. 1. One can verify that the final network configuration is a centroidal Voronoi configuration. For each evolution we depict the initial positions, the trajectories, and the final positions of all robots.

Finally, we show an evolution of limited-Voronoi-normal deployment algorithm in Fig. 2. One can verify that the final network configuration is an $\frac{r}{2}$-limited area-centered Voronoi configuration. In other words, the deployment task is achieved.

Future Directions for Research

The algorithms described above achieve locally optimal deployment configurations with respect to expected-value multicenter functions. However, this simplified setting does not account for many important constraints, such as obstacles and deployment in non-convex environments (Pimenta et al. 2008; Caicedo-Nùñez and Žefran 2008), deployment with visibility sensors, range-limited and wedge-shaped
Optimal Deployment and Spatial Coverage, Fig. 1

footprints (Ganguli et al. 2006; Laventall and Cortés 2009), and energy and vehicle dynamical restrictions (Kwok and Martínez 2010a,b). Deployment strategies find application in exploration and data gathering tasks, and so these algorithms have been expanded to account for uncertainty and learning of unknown density functions (Schwager et al. 2009; Graham and Cortés 2012; Zhong and Cassandras 2011; Martínez 2010). Gossip and self-triggered communications (Bullo et al. 2012; Nowzari and Cortés 2012), self-triggered computations for region approximation (Ru and Martínez 2013), and area equitable partitions (Cortés 2010) have also been investigated. Much work is currently being devoted to solve on the current limitations of these nontrivial extensions, which make the problem settings significantly harder to solve.

Optimal Sampled-Data Control

Yutaka Yamamoto
Department of Applied Analysis and Complex Dynamical Systems, Graduate School of Informatics, Kyoto University, Kyoto, Japan

Abstract

This article gives a brief overview on the modern development of sampled-data control. Sampled-data systems intrinsically involve a mixture of two different time sets, one continuous and the other discrete. Due to this, sampled-data systems cannot be characterized in terms of the standard notions of transfer functions, steady-state response, or frequency response. The technique of lifting resolves this difficulty and enables the recovery of such concepts and simplified solutions to sampled-data H^∞ and H^2 optimization problems. We review the lifting point of view, its application to such optimization problems, and finally present an instructive numerical example.

Keywords

Computer control; Frequency response; H^∞ and H^2 optimization; Lifting; Transfer operator

Introduction

A sampled-data control system consists of a continuous-time plant and a discrete-time controller, with sample and hold devices that serve as an interface between these two components. As can be seen from this fact, sampled-data systems are *not* time invariant, and various problems arise from this property.

To be more specific, consider the unity-feedback control system shown in Fig. 1; r is the reference signal, y the system output, and e the error signal. These are continuous-time signals. The error $e(t)$ goes through the *sampler*
Optimal Sampled-Data Control, Fig. 1 A unity-feedback system
Optimal Sampled-Data Control, Fig. 2 Sampling with 0-order hold

(or an *A/D converter*) $\mathcal{S}$. This sampler reads out the values of $e(t)$ at every time step h called the *sampling period* and produces a discrete-time signal $e_d[k]$, $k = 0, 1, 2, \ldots$ (Fig. 2). In particular, the sampling operator $\mathcal{S}$ acts on a continuous-time signal $w(t)$, $t \geq 0$, as

$$\mathcal{S}(w)[k] := w(kh), \quad k = 0, 1, 2, \ldots$$

The discretized signal is then processed by the discrete-time controller $C(z)$ and becomes a control input u_d. There can also be a quantization effect, although for the sake of simplicity this is neglected here. The obtained signal u_d then goes through another interface $\mathcal{H}$ called a *hold device* or a *D/A converter* to become a continuous-time signal. A typical example is the 0-*order hold* where $\mathcal{H}$ simply maintains the value of a discrete-time signal $w[k]$ constant as its output until the next sampling time:

$$(\mathcal{H}(w[k]))(t) := w[k], \text{ for } kh \leq t < (k+1)h.$$

A typical sample-hold action is shown in Fig. 2.

While one can consider a nonlinear plant P or controller C, or infinite-dimensional P and C we confine ourselves to linear and finite-dimensional P and C, and also suppose that P and C are time invariant in continuous time and in discrete time, respectively.

The Main Difficulty

As stated above, the unity-feedback system Fig. 1 is not time invariant either in continuous time or in discrete time, even when the plant and controller are both time invariant in their respective domains of operators. The mixture of the two time sets prohibits the total closed-loop system from being time invariant.

The lack of time-invariance implies that we cannot naturally associate to sampled-data systems such classical concepts of transfer functions, steady-state response and frequency response.

One can regard Fig. 1 as a time-invariant discrete-time system by ignoring the intersample behavior and focusing attention on the sample-point behavior only. But the obtained model does not then reflect what happens between sampling times. This approach can lead to the neglect of undesirable inter-sample oscillations, called *ripples*. To monitor the intersample behavior, the notion of the *modified z-transform* was introduced, see, e.g., Jury (1958) and Ragazzini and Franklin (1958); however, this transform is usable only *after the controller has been designed* and hence not for the design problems considered in this article.

Lifting: A Modern Approach

A new approach was introduced around 1990–1991 (Bamieh et al. 1991; Tadmor 1991; Toivonen 1992; Yamamoto 1990, 1994). The new idea, now called *lifting*, makes it possible to describe sampled-data systems via a *time-invariant model while maintaining the intersample behavior*.

Let $f(t)$ be a continuous-time signal. Instead of sampling $f(t)$, we will represent it as a *sequence* of *functions*. Namely, we set up the correspondence:

$$\mathcal{L} : f \mapsto \{f[k](\theta)\}_{k=0}^{\infty},$$
$$f[k](\theta) = f(kh + \theta), \quad 0 \le \theta < h \quad (1)$$

See Fig. 3.

This idea makes it possible to view a (time-invariant or even periodically time-varying) *continuous-time* system as a linear, *time-invariant discrete-time* system.

Let

$$\dot{x}(t) = Ax(t) + Bu(t)$$
$$y(t) = Cx(t). \tag{2}$$

be a given continuous-time plant and lift the input $u(t)$ to obtain $u[k](\cdot)$. We apply this lifted input with the timing $t = kh$ (h is the prespecified sampling rate as above) and observe how it affects the system. Let $x[k]$ be the state at time $t = kh$. The state $x[k + 1]$ at time $(k + 1)h$ is given by

$$x[k + 1] = e^{Ah}x[k] + \int_0^h e^{A(h-\tau)}Bu[k](\tau)d\tau. \tag{3}$$

The right-hand side integral defines an operator

$$L^2[0, h] \to \mathbb{R}^n : u(\cdot) \mapsto \int_0^h e^{A(h-\tau)}Bu(\tau)d\tau.$$

While the state-transition (3) only described a discrete-time update, the system keeps producing an output during the intersample period. If we consider the lifting of $x(t)$, it is easily seen to be described by

$$x[k](\theta) = e^{A\theta}x[k] + \int_0^\theta e^{A(\theta-\tau)}Bu[k](\tau)d\tau.$$

As such, the lifted output $y[k](\cdot)$ is given by

$$y[k](\theta) = Ce^{A\theta}x[k] + \int_0^\theta Ce^{A(\theta-\tau)}Bu[k](\tau)d\tau. \tag{4}$$

Observe that formulas (3) and (4) take the form

Optimal Sampled-Data Control, Fig. 3 Lifting

$$x[k + 1] = \mathcal{A}x[k] + \mathcal{B}u[k]$$

$$y[k] = \mathcal{C}x[k] + \mathcal{D}u[k],$$

and the operators $\mathcal{A}, \mathcal{B}, \mathcal{C}, \mathcal{D}$ do not depend on the time variable k. In other words, it is possible to describe this continuous-time system with discrete timing, once we adopt the lifting point of view. To be more precise, the operators $\mathcal{A}, \mathcal{B}, \mathcal{C}, \mathcal{D}$ are defined as follows:

$$\mathcal{A} : \mathbb{R}^n \to \mathbb{R}^n : x \mapsto e^{Ah}x$$
$$\mathcal{B} : L^2[0, h] \to \mathbb{R}^n : u \mapsto \int_0^h e^{A(h-\tau)}Bu(\tau)d\tau$$
$$\mathcal{C} : \mathbb{R}^n \to L^2[0, h] : x \mapsto Ce^{A(\theta)}x$$
$$\mathcal{D} : L^2[0, h] \to L^2[0, h] : u \mapsto$$
$$\int_0^\theta Ce^{A(\theta-\tau)}Bu(\tau)d\tau$$

(5)

Thus the continuous-time plant (2) can be described by a *time-invariant* discrete-time model. Once this is done, it is straightforward to connect this expression with a discrete-time controller, and hence, sampled-data systems (for example, Fig. 1) can be fully described by time-invariant discrete-time equations, without discarding the intersampling information. We will also denote the overall equation (with discrete-time controller included) abstractly in the form

$$x[k + 1] = \mathcal{A}x[k] + \mathcal{B}u[k]$$
$$y[k] = \mathcal{C}x[k] + \mathcal{D}u[k].$$

(6)

While the obtained discrete-time model is a time invariant, the input and output spaces are now infinite dimensional. Its *transfer function (operator)* is defined as

$$G(z) := \mathcal{D} + \mathcal{C}(zI - \mathcal{A})^{-1}\mathcal{B}.$$

(7)

Note that $\mathcal{A}$ in (6) is a matrix because it is so for $\mathcal{A}$ in (5). Hence, (6) is stable if $G(z)$ is analytic for $\{z : |z| \geq 1\}$, provided that there is no unstable pole-zero cancellation.

Definition 1 *Let $G(z)$ be the transfer operator of the lifted system given by (7), which is stable in the sense above. The* frequency response operator *is the operator*

$$G(e^{j\omega h}) : L^2[0, h] \to L^2[0, h]$$

(8)

regarded as a function of $\omega \in [0, \omega_s)$ ($\omega_s := 2\pi/h$). Its gain *at ω is defined to be*

$$\|G(e^{j\omega h})\| = \sup_{v \in L^2[0,h]} \frac{\|G(e^{j\omega h})v\|}{\|v\|}.$$

(9)

The maximum $\|G(e^{j\omega h})\|$ over $[0, \omega_s)$ is the H^∞ norm of $G(z)$. The H^2-norm of G is defined by

$$\|G\|_2 := \left(\frac{h}{2\pi} \int_0^{2\pi/h} trace \{G^*(e^{j\omega h})G(e^{j\omega h})\}d\omega \right)^{1/2},$$

(10)

where the trace *here is taken in the sense of Hilbert-Schmidt norm; see Chen and Francis (1995) for details.*

H^∞ and H^2 Control Problems

A significant consequence of the lifting approach described above is that various robust control problems such as H^∞ and H^2 control problems for sampled-data control systems can be converted to corresponding discrete-time (finite-dimensional) problems. The approach was initiated by Chen and Francis (1990) and later solved by Bamieh and Pearson (1992), Kabamba and Hara (1993), Sivashankar and Khargonekar (1994), Tadmor (1991), and Toivonen (1992) in more complete forms; see Chen and Francis (1995) for the pertinent historical accounts.

Let us introduce the notion of generalized plants. Suppose that a continuous time plant is given in the following model:

$$\dot{x}_c(t) = Ax_c(t) + B_1w(t) + B_2u(t)$$
$$z(t) = C_1x_c(t) + D_{11}w(t) + D_{12}u(t) \quad (11)$$
$$y(t) = C_2x_c(t)$$

Here w is the exogenous input, $u(t)$ control input, $y(t)$ measured output, and $z(t)$ is the controlled output. The objective is to design a controller that takes the sampled measurements of y and returns a control variable u according to the following formula:

$$x_d[k + 1] = A_dx_d[k] + B_d\mathcal{S}y[k]$$
$$v[k] = C_dx_d[k] + D_d\mathcal{S}y[k] \quad (12)$$
$$u[k](\theta) = H(\theta)v[k]$$
Optimal Sampled-Data Control, Fig. 4 Sampled feedback system

where $H(\theta)$ is a suitable hold function. This is depicted in Fig. 4. The objective here is to design or characterize a controller that achieves a prescribed performance level $\gamma > 0$ in such a way that

$$\|T_{zw}\|_\infty < \gamma \qquad (13)$$

where T_{zw} denotes the closed-loop transfer operator from w to z. This is the H^∞ control problem for sampled-data systems. If we take the H^2-norm (10) instead, then the problem becomes that of the H^2 (sub)optimal control problem.

The difficulty here is that both w and z are continuous-time variables, and hence their lifted variables are infinite dimensional. A remarkable fact here is that the H^∞ problem (and the H^2 problem as well) (13) can be equivalently transformed to an H^∞ problem for a *finite-dimensional* discrete-time system. We will indicate in the next section how this can be done.

H^∞ Norm Computation and Reduction to Finite Dimension

Let us write the system (11) and (12) in the form

$$\begin{aligned} x[k+1] &= \mathcal{A}x[k] + \mathcal{B}u[k] \\ y[k] &= \mathcal{C}x[k] + \mathcal{D}u[k]. \end{aligned} \qquad (14)$$

as in (6). For simplicity of treatments, assume D_{11} in (11) to be zero; for the general case, see Yamamoto and Khargonekar (1996).

Let $G(z)$ be the transfer operator $G(z) := \mathcal{D} + \mathcal{C}(zI - \mathcal{A})^{-1}\mathcal{B}$. The H^∞ norm of G is given as the maximum of the singular values of the gain $G(e^{j\omega h})$ for $\omega \in [0, 2\pi/h)$.

Now consider the singular value equation

$$(\gamma^2 I - G^*G(e^{j\omega h}))w = 0. \qquad (15)$$

and suppose that $\gamma > \|\mathcal{D}\|$. A crux here is that $\mathcal{A}, \mathcal{B}, \mathcal{C}$ are finite-rank operators, and we can reduce this to a finite-dimensional rank condition. Taking the adjoint of (14), we obtain

$$\begin{aligned} p[k] &= \mathcal{A}^* p_{k+1} + \mathcal{C}^* v[k] \\ e[k] &= \mathcal{B}^* p_{k+1} + \mathcal{D}^* v[k]. \end{aligned}$$

Taking the z-transforms of both sides, setting $z = e^{j\omega h}$, and substituting $v = y$ and $e = \gamma^2 w$, we obtain

$$\begin{aligned} e^{j\omega h}x &= \mathcal{A}x + \mathcal{B}w \\ p &= e^{j\omega h}\mathcal{A}^* p + \mathcal{C}^*(\mathcal{C}x + \mathcal{D}w) \\ (\gamma^2 - \mathcal{D}^*\mathcal{D})w &= e^{j\omega h}\mathcal{B}^* p + \mathcal{D}^*\mathcal{C}x. \end{aligned}$$

Eliminating the variable w then yields

$$\left(e^{j\omega h} \begin{bmatrix} I & \mathcal{B}R_\gamma^{-1}\mathcal{B}^* \\ 0 & \mathcal{A}^* + \mathcal{C}^*\mathcal{D}R_\gamma^{-1}\mathcal{B}^* \end{bmatrix} - \begin{bmatrix} \mathcal{A} + \mathcal{B}R_\gamma^{-1}\mathcal{D}^*\mathcal{C} & 0 \\ \mathcal{C}^*(I + \mathcal{D}R_\gamma^{-1}\mathcal{D}^*)\mathcal{C} & I \end{bmatrix} \right) \begin{bmatrix} x \\ p \end{bmatrix} = 0 \qquad (16)$$

where $R_\gamma = (\gamma I - \mathcal{D}^*\mathcal{D})$. The important point to be noted here is that all the operators appearing here are actually matrices. For example, $\mathcal{B}$ is an

operator from $L^2[0, h]$ to $\mathbb{R}^n$, and its adjoint $\mathcal{B}^*$ is an operator from $\mathbb{R}^n$ to $L^2[0, h]$. Hence, the composition $\mathcal{B}R_\gamma^{-1}\mathcal{B}^*$ is a linear operator from

$\mathbb{R}^n$ into itself, i.e., a matrix. Thus, for a given γ the singular value equation admits a nontrivial solution w for (15) if and only if the *finite-dimensional equation* (16) admits a nontrivial solution $\begin{bmatrix} x & p \end{bmatrix}^T$ (Yamamoto 1993; Yamamoto and Khargonekar 1996). (Note that R_γ is invertible since $\gamma > \|\mathcal{D}\|$.)

It is possible to find matrices $\overline{A}, \overline{B}, \overline{C}$ such that $\overline{A} = \mathcal{A} + \mathcal{B}R_\gamma^{-1}\mathcal{D}^*\mathcal{C}$, $\overline{B}\,\overline{B}^*/\gamma^2 = \mathcal{B}R_\gamma^{-1}\mathcal{B}^*$, and $\overline{C}^*\overline{C} = \mathcal{C}^*(I + \mathcal{D}R_\gamma^{-1}\mathcal{D}^*)\mathcal{C}$, and hence (16) is equivalent to

$$\left(\lambda \begin{bmatrix} I & -\overline{B}\,\overline{B}^*/\gamma^2 \\ 0 & \overline{A}^* \end{bmatrix} - \begin{bmatrix} \overline{A} & 0 \\ -\overline{C}^*\overline{C} & I \end{bmatrix} \right) \begin{bmatrix} x \\ p \end{bmatrix} = 0 \tag{17}$$

for $\lambda = e^{j\omega h}$. In other words, we have that $\|G\|_\infty < \gamma$ if and only if there exists no λ of modulus 1 such that (17) holds.

It can be proven that by substituting the expressions of (11) and (12) for $(\mathcal{A}, \mathcal{B}, \mathcal{C}, \mathcal{D})$, one obtains a finite-dimensional discrete-time generalized plant G_d with digital controller (12) such that $\|G\|_\infty < \gamma$ if and only if $\|G_d\|_\infty < \gamma$. The precise formulas for the discrete-time plant can be found, e.g., Bamieh and Pearson (1992), Chen and Francis (1995), Kabamba and Hara (1993), Yamamoto and Khargonekar (1996), and Cantoni and Glover (1997).

An H^∞ Design Example

For sampled-data control systems, there used to be, and still is, a rather common myth that if one takes a sufficiently fast sampling rate, it will not cause a major problem. This can be true for continuous-time design, but we here show that if we employ a sample-point discretization without a performance consideration for intersampling behavior, fast sampling rates can cause a serious problem.

Take a simple second-order plant $P(s) = 1/(s^2 + 0.1s + 1)$, and consider the disturbance rejection problem minimizing the H^∞-norm from w to z as given in Fig. 5. Set the sampling time $h = 0.5$. We execute the following:

- Sampled-data H^∞ design with the generalized plant

$$G(s) = \begin{bmatrix} P(s) & P(s) \\ P(s) & P(s) \end{bmatrix},$$

- Discrete-time H^∞ design with the discrete-time generalized plant $G_d(z)$ given by the step-invariant transformation (see, e.g., Chen and Francis 1995) of $G(s)$.

Figures 6 and 7 show the frequency and time responses of the two resulting closed-loop systems, respectively. In Fig. 6, the solid curve shows the response of the sampled design, while the dash-dotted curve shows the discrete-time frequency response, but purely reflecting its sample-point behavior only. At first glance, it may appear that the discrete-time design performs better. But when we actually compute the lifted sampled-data frequency response in the sense defined in Definition 1, it becomes obvious that the sampled-data design is far superior. The dashed curve shows the frequency response of the closed-loop, i.e., that of $G(s)$ connected with the discrete-time designed K_d. The response is similar to the discrete-time frequency response in low frequency, but exhibits a very sharp peak around the Nyquist frequency (i.e., half the sampling frequency; in the present case, $\pi/h \sim 6.28$ rad/s, i.e., $1/2h = 1$ Hz).

This can also be verified from the initial-state responses Fig. 7 with $x(0) = (1, 1)$. The solid curve shows the sampled-data design and the dashed curve the discrete-time one. Both responses decay to zero rapidly *at sampled instants* as shown by the circles for the discrete-time design. But the discrete-time design exhibits very large ripples, with period approximately 1 s. This corresponds to 1 Hz, which is the same as $2\pi = \pi/h$ [rad/s], i.e., the Nyquist frequency. This is precisely captured in the lifted frequency response in Fig. 6.

It is worth noting that when we take the sampling period h smaller, the response for the discrete-time design becomes even more oscillatory and shows a very high peak in the frequency response.

Summary, Bibliographical Notes, and Future Directions

We have given a short summary of the main achievements of modern sampled-data control theory. Particularly, we have reviewed how the technique of lifting resolved the intrinsic difficulty arising from the mixture of two distinct time sets: continuous and discrete. This idea further led to the new notions of transfer operators and frequency response. These notions together enabled us to treat optimal sampled-data control problems in a unified and transparent way. We have outlined how the sampled-data H^∞ control problem can equivalently be reduced to a corresponding discrete-time H^∞ problem, without sacrificing the performance in the intersample behavior. This has been exemplified by a numerical example.

There are other performance indices for optimality, typically those arising from H^2 and L^1 norms. These problems have also been studied extensively, and fairly complete solutions are available. For the lack of space, we cannot list all references, and the reader is referred to Chen and Francis (1995) and Yamamoto (1999) for a more concrete survey and references therein.

For classical treatments of sampled-data control, it is instructive to consult Jury (1958) and Ragazzini and Franklin (1958). The textbook Åström and Wittenmark (1996) covers both classical and modern aspects of digital control. For a mathematical background of the computation of adjoints treated in section "H^∞ Norm Computation and Reduction to Finite Dimension," consult Yamamoto (2012) as well as Yamamoto (1993).

Since control devices are now mostly digital, the importance of sampled-data control will
Optimal Sampled-Data Control, Fig. 7 Initial-state responses $h = 0.5$

definitely increase. While the linear, time-invariant case as treated here is now fairly complete, sampled-data control for a nonlinear or an infinite-dimensional plant seems to be still quite an open issue, although it is unclear if the methodology treated here is effective for such classes of plants.

Sampled-data control has much to do with signal processing. Indeed, since it can optimize continuous-time performance, it can shed a new light on digital signal processing. Traditionally, Shannon's paradigm based on the perfect band-limiting hypothesis and the sampling theorem has been prevalent in the signal processing community. Since the sampling theorem opts for perfect reconstruction, the resulting theory reduces mostly to discrete-time problems. In other words, the intersample information is buried in the sampling theorem. It should, however, be noted that the very stringent band-limiting hypothesis is almost never satisfied in reality, and various approximations are necessitated. In contrast, sampled-data control can provide an optimal platform for dealing with and optimizing the response between sampling

points when the band-limiting hypothesis does not hold. See, for example, Yamamoto et al. (2012) and Nagahara and Yamamoto (2012) for the idea and some efforts in this direction.

Abstract

This entry reviews optimization algorithms for both linear and nonlinear model predictive control (MPC). Linear MPC typically leads to specially structured convex quadratic programs (QP) that can be solved by structure exploiting active set, interior point, or gradient methods. Nonlinear MPC leads to specially structured nonlinear programs (NLP) that can be solved by sequential quadratic programming (SQP) or nonlinear interior point methods.

Keywords

Banded matrix factorization; Convex optimization; Karush-Kuhn-Tucker (KKT) conditions; Sparsity exploitation

Introduction

Model predictive control (MPC) needs to solve at each sampling instant an optimal control problem with the current system state $\bar{x}_0$ as initial value. MPC optimization is almost exclusively based on the so-called *direct approach* which first discretizes the continuous time system to obtain a discrete time optimal control problem (OCP). This OCP has as optimization variables a state trajectory $X = [x_0^\top, \ldots, x_N^\top]^\top$ with $x_i \in \mathbb{R}^{n_x}$ for $i = 0, \ldots, N$ and a control trajectory $U = [u_0^\top, \ldots, u_{N-1}^\top]^\top$ with $u_i \in \mathbb{R}^{n_u}$ for $i = 0, \ldots, N - 1$. For simplicity of presentation, we

restrict ourselves to the time-independent case, and the OCP we treat in this article is stated as follows:

$$\underset{X, U}{\text{minimize}} \quad \sum_{i=0}^{N-1} L(x_i, u_i) \; + \; E\left(x_N\right) \qquad \text{(1a)}$$

$$\text{subject to} \quad x_0 - \bar{x}_0 = 0, \qquad\qquad\qquad \text{(1b)}$$

$$x_{i+1} - f(x_i, u_i) = 0, \quad i = 0, \ldots, N-1, \qquad \text{(1c)}$$

$$h(x_i, u_i) \leq 0, \quad i = 0, \ldots, N-1, \qquad \text{(1d)}$$

$$r\left(x_N\right) \leq 0. \qquad\qquad\qquad \text{(1e)}$$

The MPC objective is stated in Eq. (1a), the system dynamics enter via Eq. (1c), while path and terminal constraints enter via Eqs. (1d) and (1e). All functions are assumed to be differentiable and to have appropriate dimensions ($h(x, u) \in \mathbb{R}^{n_h}$ and $r(x) \in \mathbb{R}^{n_r}$). Note that $\bar{x}_0 \in \mathbb{R}^{n_x}$ is not an optimization variable, but a parameter upon which the OCP depends via the initial value constraint in Eq. (1b). The optimal solution trajectories depend only on this value and can thus be denoted by $X^*(\bar{x}_0)$ and $U^*(\bar{x}_0)$. Obtaining them, in particular the first control value $u_0^*(\bar{x}_0)$, as fast and reliably as possible for each new value of $\bar{x}_0$ is the aim of all MPC optimization algorithms. The most important dividing line is between convex and non-convex optimal control problems (OCP). If the OCP is convex, algorithms exist that find a global solution reliably and in computable time. If the OCP is not convex, one usually needs to be satisfied with approximations of locally optimal solutions. The OCP (1) is convex if the objective (1a) and all components of the inequality constraint functions (1d) and (1e) are convex and if the equality constraints (1c) are linear.

We typically speak of *linear MPC* when the OCP to be solved is convex, and otherwise of *nonlinear MPC*.

General Algorithmic Features for MPC Optimization

In MPC we would dream to have the solution to a new optimal control problem instantly, which is impossible due to computational delays. Several ideas can help us to deal with this issue.

Off-line Precomputations and Code Generation

As consecutive MPC problems are similar and differ only in the value $\bar{x}_0$, many computations can be done once and for all before the MPC controller execution starts. Careful preprocessing and code optimization for the model routines is essential, and many tools automatically generate custom solvers in low-level languages. The generated code has fixed matrix and vector dimensions, has no online memory allocations, and contains a minimal number of if-then-else statements to ensure a smooth computational flow.

Delay Compensation by Prediction

When we know how long our computations for solving an MPC problem will take, it is a good idea *not* to address a problem starting at the current state but to simulate at which state the system will be when we will have solved the problem. This can be done using the MPC system model and the open-loop control inputs that we will apply in the meantime. This feature is used in many practical MPC schemes with non-negligible computation time.

Division into Preparation and Feedback Phase

A third ingredient of several MPC algorithms is to divide the computations in each sampling time into a preparation phase and a feedback phase. The more CPU intensive *preparation phase* is performed with a predicted state $\bar{x}_0$, before the most current state estimate, say $\bar{x}_0'$, is available. Once $\bar{x}_0'$ is available, the *feedback phase* delivers quickly an *approximate* solution to the optimization problem for $\bar{x}_0'$.

Warmstarting and Shift

An obvious way to transfer solution information from one solved MPC problem to the next one uses the existing optimal solution as an initial guess to start the iterative solution procedure of the next problem. We can either directly use the existing solution without modification for warmstarting or we can first shift it in order to

account for the advancement of time, which is particularly advantageous for systems with time-varying dynamics or objectives.

Iterating While the Problem Changes

A last important ingredient of some MPC algorithms is the idea to work on the optimization problem while it changes, i.e., to never iterate the optimization procedure to convergence for an MPC problem getting older and older during the iterations but to rather work with the most current information in each new iteration.

Convex Optimization for Linear MPC

Linear MPC is based on a linear system model of the form $x_{i+1} = Ax_i + Bu_i$ and convex objective and constraint functions in (1a), (1d), and (1e). The most widespread linear MPC setting uses a convex quadratic objective function and affine constraints and solves the following quadratic program (QP):

$$\underset{X, U}{\text{minimize}} \quad \frac{1}{2} \sum_{i=0}^{N-1} \begin{bmatrix} x_i \\ u_i \end{bmatrix}^\top \begin{bmatrix} Q & S \\ S^\top & R \end{bmatrix} \begin{bmatrix} x_i \\ u_i \end{bmatrix} + \frac{1}{2} x_N^\top P x_N \tag{2a}$$

subject to
$$x_0 - \bar{x}_0 = 0, \tag{2b}$$

$$x_{i+1} - Ax_i - Bu_i = 0, i = 0, \dots, N-1, \tag{2c}$$

$$b + Cx_i + Du_i \leq 0, i = 0, \dots, N-1, \tag{2d}$$

$$c + Fx_N \leq 0. \tag{2e}$$

Here, b, c are vectors and Q, S, R, P, C, D, F matrices, and matrices $\begin{bmatrix} Q & S \\ S^\top & R \end{bmatrix}$ and P are symmetric and positive semi-definite to ensure the QP is convex.

Sparsity Exploitation

The QP (2) has a specific sparsity structure that can be exploited in different ways. One way is to reduce the variable space by a procedure called *condensing* and then to solve a smaller-scale QP

instead of (2). Another way is to use a *banded matrix factorization*.

Condensing

The constraints (2b) and (2c) can be used to eliminate the state trajectory X. This yields an equivalent but smaller-scale QP of the following form:

$$\underset{U \in \mathbb{R}^{Nn_u}}{\text{minimize}} \quad \frac{1}{2} \begin{bmatrix} U \\ \bar{x}_0 \end{bmatrix}^\top \begin{bmatrix} H & G \\ G^\top & J \end{bmatrix} \begin{bmatrix} U \\ \bar{x}_0 \end{bmatrix} \tag{3a}$$

subject to $\quad d + K\bar{x}_0 + MU \leq 0. \tag{3b}$

The number of inequality constraints is the same as in the original QP (2) and given by $m = Nn_h + n_r$. Note that in the simplest case without inequalities ($m = 0$), the solution $U^*(\bar{x}_0)$ of the condensed QP can be obtained by setting the gradient of the objective to zero, i.e., by solving $HU^*(\bar{x}_0) + G\bar{x}_0 = 0$. The factorization of a dense matrix H with dimension $Nn_u \times Nn_u$ needs $O(N^3 n_u^3)$ arithmetic operations, i.e., the computational cost of condensing-based algorithms typically grows cubically with the horizon length N.

Banded Matrix Factorization

An alternative way to deal with the sparsity is best sketched at hand of a sparse convex QP (2) without inequality constraints (2d) and (2e). We define the vector of Lagrange multipliers $Y = [y_0^\top, \dots, y_N^\top]^\top$ and the Lagrangian function by

$$\mathcal{L}(X, U, Y) = y_0^\top (x_0 - \bar{x}_0) + \frac{1}{2} x_N^\top P x_N$$
$$+ \frac{1}{2} \sum_{i=0}^{N-1} \begin{bmatrix} x_i \\ u_i \end{bmatrix}^\top \begin{bmatrix} Q & S \\ S^\top & R \end{bmatrix} \begin{bmatrix} x_i \\ u_i \end{bmatrix} + y_{i+1}^\top$$
$$(x_{i+1} - Ax_i + Bu_i). \tag{4}$$

If we reorder all unknowns that enter the Lagrangian and summarize them in the vector

$$W = [y_0^\top, x_0^\top, u_0^\top, y_1^\top, x_1^\top, u_1^\top, \dots, y_N^\top, x_N^\top]^\top$$

the optimal solution $W^*(\bar{x}_0)$ is uniquely characterized by the first-order optimality condition

O

$$\nabla_W \mathcal{L}(W^*) = 0.$$

Due to the linear quadratic dependence of $\mathcal{L}$ on W, this is a block-banded linear equation in the unknown W^*:

$$\begin{bmatrix} 0 & I & & & & & & \\ I & Q & S & -A^\top & & & & \\ & S^\top & R & -B^\top & & & & \\ & -A & -B & 0 & I & & & \\ & & & I & Q & \cdot & \cdot & \\ & & & & \cdot & \cdot & \cdot & \\ & & & & \cdot & \cdot & 0 & I \\ & & & & & & I & P \end{bmatrix} W^* = \begin{bmatrix} \bar{x}_0 \\ 0 \\ 0 \\ 0 \\ \cdot \\ \cdot \\ \cdot \\ 0 \end{bmatrix}.$$

Because the above matrix has nonzero elements only on a band of width $2n_x + n_u$ around the diagonal, it can be factorized with a computational cost of order $O(N(2n_x + n_u)^3)$.

Treatment of Inequalities

An important observation is that both the uncondensed QP (2) and the equivalent condensed QP (3) typically fall into the class of strictly convex parametric quadratic programs: the solution $U^*(\bar{x}_0)$, $X^*(\bar{x}_0)$ is unique and depends piecewise affinely and continuously on the parameter $\bar{x}_0$. Each affine piece of the solution map corresponds to one *active set* and is valid on one polyhedral *critical region* in parameter space. This observation forms the basis of *explicit MPC algorithms* which precompute the map $u_0^*(\bar{x}_0)$, but it can also be exploited in online algorithms for quadratic programming, which are the focus of this section.

We sketch the different ways of how to treat inequalities only for the condensed QP (3), but they can equally be applied in sparse QP algorithms that directly address (2). The optimal solution $U^*(\bar{x}_0)$ for a strictly convex QP (3) is – together with the corresponding vector of Lagrange multipliers, or dual variables $\lambda^*(\bar{x}_0) \in \mathbb{R}^m$ – uniquely characterized by the so-called Karush-Kuhn-Tucker (KKT) conditions, which we omit for brevity. There are three big families of solution algorithms for inequality-constrained QPs that differ in the way they treat inequalities: *active set methods*, *interior point methods*, and *gradient projection methods*.

Active Set Methods

The optimal solution of the QP is characterized by its *active set*, i.e., the set of inequality constraints (3b) that are satisfied with equality at this point. If one would know the active set for a given problem instance $\bar{x}_0$, it would be easy to find the solution. Active set methods work with guesses of the active set which they iteratively refine. In each iteration, they solve one linear system corresponding to a given guess of the active set. If the KKT conditions are satisfied, the optimal solution is found; if they are not, another division into active and inactive constraints needs to be tried. A crucial observation is that an existing factorization of the linear system can be reused to a large extent when only one constraint is added or removed from the guess of the active set. Many different active set strategies exist, three of which we mention: *Primal active set methods* first find a feasible point and then add or remove active constraints, always keeping the primal variables U feasible. Due to the difficulty of finding a feasible point first, they are difficult to warmstart in the context of MPC optimization. *Dual active set strategies* always keep the dual variables λ positive. They can easily be warmstarted in the context of MPC. *Parametric* or *online active set strategies* ensure that all iterates stay primal and dual feasible and go on a straight line in parameter space from a solved QP problem to the current one, only updating the active set when crossing the boundary between critical regions, as implemented in the online QP solver qpOASES.

Active set methods are very competitive in practice, but their worst case complexity is not polynomial. They are often used together with the condensed QP formulation, for which each active set change is relatively cheap. This is particularly advantageous if an existing factorization can be kept between subsequent MPC optimization problems.

Interior Point Methods

Another approach is to replace the KKT conditions by a smooth approximation that uses a small positive parameter $\tau > 0$:

$$HU^* + G\bar{x}_0 + M^\top \lambda^* = 0, \tag{5a}$$

$$\left(d + K\bar{x}_0 + MU^*\right)_i \lambda_i^* + \tau = 0, \ i = 1, \ldots, m.$$
(5b)

These conditions form a smooth nonlinear system of equations that uniquely determines a primal dual solution $U^*(\bar{x}_0, \tau)$ and $\lambda^*(\bar{x}_0, \tau)$ in the interior of the feasible set. They are not equivalent to the KKT conditions, but for $\tau \to 0$, their solution tends to the exact QP solution. An interior point algorithm solves the system (5a) and (5b) by Newton's method. Simultaneously, the path parameter τ, that was initially set to a large value, is iteratively reduced, making the nonlinear set of equations a closer approximation of the original KKT system. In each Newton iteration, a linear system needs to be factored and solved, which constitutes the major computational cost of an interior point algorithm. For the condensed QP (3) with dense matrices H, M, the cost per Newton iteration is of order $O(N^3)$. But the interior point algorithm can also be applied to the uncondensed sparse QP (2), in which case each iteration has a runtime of order $O(N)$. In practice, for both cases, 10–30 Newton iterations usually suffice to obtain very accurate solutions. As an interior point method needs always to start with a high value of τ and then reduces it during the iterations, warmstarting is of minor benefit. There exist efficient code generation tools that export convex interior point solvers as plain C-code such as CVXGEN and FORCES.

Gradient Projection Methods
Gradient projection methods do not need to factorize any matrix but only evaluate the gradient of the objective function $HU^{[k]} + G\bar{x}_0$ in each iteration. They can only be implemented efficiently if the feasible set is a simple set in the sense that a projection $\mathcal{P}(U)$ on this set is very cheap to compute, as, e.g., for upper and lower bounds on the variables U, and if we know an upper bound $L_H > 0$ on the eigenvalues of the Hessian H. The simple gradient projection algorithm starts with an initialization $U^{[0]}$ and proceeds as follows:

$$U^{[k+1]} = \mathcal{P}\left(U^{[k]} - \frac{1}{L_H}(HU^{[k]} + G\bar{x}_0)\right).$$

An improved version of the gradient projection algorithm is called the *optimal* or *fast gradient method* and has probably the best possible iteration complexity of all gradient type methods. All variants of gradient projection algorithms are easy to warmstart. Though they are not as versatile as active set or interior point methods, they have short code sizes and can offer advantages on embedded computational hardware, such as the code generated by the tool FIOR-DOS.

Optimization Algorithms for Nonlinear MPC

When the dynamic system $x_{i+1} = f(x_i, u_i)$ is not affine, the optimal control problem (1) is non-convex, and we speak of a nonlinear MPC (NMPC) problem. NMPC optimization algorithms only aim at finding a locally optimal solution of this problem, and they usually do it in a Newton-type framework. For ease of notation, we summarize problem (1) in the form of a general nonlinear programming problem (NLP):

$$\begin{aligned}
\underset{X, U}{\text{minimize}} \quad & \Phi(X, U) && \text{(6a)} \\
\text{subject to} \quad & G_{\text{eq}}(X, U, \bar{x}_0) = 0, && \text{(6b)} \\
& G_{\text{ineq}}(X, U) \leq 0. && \text{(6c)}
\end{aligned}$$

Let us first discuss a fundamental choice that regards the problem formulation and number of optimization variables.

Simultaneous vs. Sequential Formulation
When an optimization algorithm addresses problem (6) iteratively, it works intermediately with nonphysical, infeasible trajectories that violate the system constraints (6b). Only at the optimal solution the constraint residual is brought to zero and a physical simulation is achieved. We speak

of a *simultaneous approach* to optimal control because the algorithm solves the simulation and the optimization problems simultaneously. Variants of this approach are *direct discretization* or *direct multiple shooting*.

On the other hand, the equality constraints (6b) could easily be eliminated by a nonlinear forward simulation for given initial value $\bar{x}_0$ and control trajectory U, similar to condensing in linear MPC. Such a forward simulation generates a state trajectory $X_{\text{sim}}(\bar{x}_0, U)$ such that for the given value of $\bar{x}_0, U$ the equality constraints (6b) are automatically satisfied: $G_{\text{eq}}(X_{\text{sim}}(\bar{x}_0, U), U, \bar{x}_0) = 0$. Inserting this map into the NLP (6) allows us to formulate an equivalent optimization problem with a reduced variable space:

$$\underset{U}{\text{minimize}} \qquad \Phi(X_{\text{sim}}(\bar{x}_0, U), U) \qquad (7a)$$

$$\text{subject to} \quad G_{\text{ineq}}(X_{\text{sim}}(\bar{x}_0, U), U) \leq 0. \quad (7b)$$

When solving this reduced problem with an iterative optimization algorithm, we sequentially simulate and optimize the system, and we speak of the *sequential approach* to optimal control.

The sequential approach has a lower dimensional variable space and is thus easier to use with a black-box NLP solver. On the other hand, the simultaneous approach leads to a sparse NLP and is better able to deal with unstable nonlinear systems. In the remainder of this section, we thus only discuss the specific structure of the simultaneous approach.

Newton-Type Optimization

In order to simplify notation further, we summarize and reorder all optimization variables U and X in a vector $V = [x_0^\top, u_0^\top, \ldots, x_{N-1}^\top, u_{N-1}^\top, x_N^\top]^\top$ and use the same problem function names as in (6) also with the new argument V.

As in the section on linear MPC, we can introduce multipliers Y for the equalities and λ for the inequalities and define the Lagrangian

$$\mathcal{L}(V, Y, \lambda) = \Phi(V) + Y^\top G_{\text{eq}}(V, \bar{x}_0)$$

$$+ \lambda^\top G_{\text{ineq}}(V). \qquad (8)$$

All Newton-type optimization methods try to find a point satisfying the KKT conditions by using successive linearizations of the problem functions and Lagrangian. For this aim, starting with an initial guess $(V^{[0]}, Y^{[0]}, \lambda^{[0]})$, they generate sequences of primal-dual iterates $(V^{[k]}, Y^{[k]}, \lambda^{[k]})$.

An observation that is crucial for the efficiency of all NMPC algorithms is that the Hessian of the Lagrangian is at a current iterate given by a matrix of the form

$$\nabla_V^2 \mathcal{L}(\cdot) = \begin{bmatrix} Q_0^{[k]} & S_0^{[k]} & & & & \\ S_0^{[k],\top} & R_0^{[k]} & & & & \\ & & Q_1^{[k]} & S_1^{[k]} & & \\ & & S_1^{[k],\top} & R_1^{[k]} & & \\ & & & & \ddots & \\ & & & & & \ddots & \\ & & & & & & P^{[k]} \end{bmatrix}.$$

This block sparse matrix structure makes it possible to use in each Newton-type iteration the same sparsity-exploiting linear algebra techniques as outlined in section "Convex Optimization for Linear MPC" for the linear MPC problem.

Major differences exist on how to treat the inequality constraints, and the two big families of Newton-type optimization methods are *sequential quadratic programming (SQP)* methods and *nonlinear interior point (NIP)* methods.

Sequential Quadratic Programming (SQP)

A first variant to iteratively solve the KKT system is to linearize all nonlinear functions at the current iterate $(V^{[k]}, Y^{[k]}, \lambda^{[k]})$ and to find a new solution guess from the solution of a quadratic program (QP):

$$\underset{V}{\text{minimize}} \qquad \Phi_{\text{quad}}(V; V^{[k]}, Y^{[k]}, \lambda^{[k]}) \qquad (9a)$$

$$\text{subject to} \qquad G_{\text{eq,lin}}(V, \bar{x}_0; V^{[k]}) = 0, \qquad (9b)$$

$$G_{\text{ineq,lin}}(V; V^{[k]}) \leq 0. \qquad (9c)$$

Here, the subindex "lin" in the constraints $G_{\cdot,\text{lin}}$ expresses that a first-order Taylor expansion at

$V^{[k]}$ is used, while the QP objective is given by $\Phi_{\text{quad}}(V; V^{[k]}, Y^{[k]}, \lambda^{[k]}) = \Phi_{\text{lin}}(V; V^{[k]}) + \frac{1}{2}(V - V^{[k]})^\top \nabla_V^2 \mathcal{L}(\cdot)(V - V^{[k]})$. Note that the QP has the same sparsity structure as the QP (2) resulting from linear MPC, with the only difference that all matrices are now time varying over the MPC horizon. In the case that the Hessian matrix is positive semi-definite, this QP is convex so that global solutions can be found reliably with any of the methods from section "Convex Optimization for Linear MPC." The solution of the QP along with the corresponding constraint multipliers gives the next SQP iterate $(V^{[k+1]}, Y^{[k+1]}, \lambda^{[k+1]})$. Apart from the presented "exact Hessian" SQP variant, which has quadratic convergence speed, several other SQP variants exist, which make use of other Hessian approximations. A particularly useful Hessian approximation for NMPC is possible if the original objective function $\Phi(V)$ is convex quadratic, and the resulting SQP variant is called the *generalized Gauss-Newton* method. In this case, one can just use the original objective as cost function in the QP (9a), resulting in convex QP subproblems and (often fast) linear convergence speed.

Nonlinear Interior Point (NIP) Method

In contrast to SQP methods, an alternative way to address the solution of the KKT system is to replace the last nonsmooth KKT conditions by a smooth nonlinear approximation, with $\tau > 0$:

$$\nabla_V \mathcal{L}(V^*, Y^*, \lambda^*) = 0 \qquad (10a)$$

$$G_{\text{eq}}(V^*, \bar{x}_0) = 0 \qquad (10b)$$

$$G_{\text{ineq},i}(V^*)\,\lambda_i^* + \tau = 0, \quad i = 1, \dots, m. \qquad (10c)$$

We summarize all variables in a vector $W = [V^\top, Y^\top, \lambda^\top]^\top$ and summarize the above set of equations as

$$G_{\text{NIP}}(W, \bar{x}_0, \tau) = 0. \qquad (11)$$

The resulting root finding problem is then solved with Newton's method, for a descending sequence of path parameters $\tau^{[k]}$. The NIP method proceeds thus exactly as in an interior point method for convex problems, with the only difference that it has to re-linearize all problem functions in each iteration. An excellent software implementation of the NIP method is given in the form of the code IPOPT.

Continuation Methods and Tangential Predictors

In nonlinear MPC, a sequence of OCPs with different initial values $\bar{x}_0^{[0]}, \bar{x}_0^{[1]}, \bar{x}_0^{[2]}, \dots$ is solved. For the transition from one problem to the next, it is beneficial to take into account the fact that the optimal solution $W^*(\bar{x}_0)$ depends almost everywhere differentiably on $\bar{x}_0$. The concept of a continuation method is most easily explained in the context of an NIP method with fixed path parameter $\bar{\tau} > 0$. In this case, the solution $W^*(\bar{x}_0, \bar{\tau})$ of the smooth root finding problem $G_{\text{NIP}}(W^*(\bar{x}_0, \bar{\tau}), \bar{x}_0, \bar{\tau}) = 0$ from Eq. (11) is smooth with respect to $\bar{x}_0$. This smoothness can be exploited by making use of a *tangential predictor* in the transition from one value of $\bar{x}_0$ to another. Unfortunately, the interior point solution manifold is strongly nonlinear at points where the active set changes, and the tangential predictor is not a good approximation when we linearize at such points.

Generalized Tangential Predictor and Real-Time Iterations

In fact, the true NLP solution is not determined by a smooth root finding problem (10a)–(3) but by the (nonsmooth) KKT conditions. The solution manifold has smooth parts when the active set does not change, but non-differentiable points occur whenever the active set changes. We can deal with this fact naturally in an SQP framework by solving one QP of form (9) in order to generate a tangential predictor that is also valid in the presence of active set changes. In the extreme case that only one such QP is solved per sampling time, we speak of a *real-time iteration (RTI)* algorithm. The computations in each iteration can be subdivided into two phases, the *preparation phase*, in which the derivatives are computed and the QP is condensed, and the *feedback phase*, which

only starts once $\bar{x}_0^{[k+1]}$ becomes available and in which only a condensed QP of form (3) is solved, minimizing the feedback delay. This NMPC algorithm can be generated as plain C-code, e.g., by the tool ACADO. Another class of real-time NMPC algorithms based on a continuation method can be generated by the tool AutoGenU.

Abstract

This entry describes the basic setup of linear robust control and the difficulties typically encountered when designing optimization algorithms to cope with robust stability and performance specifications.

Keywords

Linear systems; Optimization; Robust control

Linear Robust Control

Robust control allows dealing with uncertainty affecting a dynamical system and its environment. In this section, we assume that we have a mathematical model of the dynamical system without uncertainty (the so-called nominal system) jointly with a mathematical model of the uncertainty. We restrict ourselves to **linear systems**: if the dynamical system we want to control has some nonlinear components (e.g., input saturation), they must be embedded in the uncertainty model. Similarly, we assume that the control system is relatively small scale (low number of states): higher-order dynamics (e.g., highly oscillatory but low energy components) are embedded in the uncertainty model. Finally, for conciseness, we focus exclusively on continuous-time systems, even though most of the techniques described in this section can be transposed readily to discrete-time systems.

Our control system is described by the first-order ordinary differential equation

$$\dot{x} = A(\delta) x + D(\delta) u$$
$$y = C(\delta) x$$

where as usual $x \in \mathbb{R}^n$ denotes the states, $u \in \mathbb{R}^m$ denotes the controlled inputs, and $y \in \mathbb{R}^p$ denotes the measured outputs, all depending on time t, with $\dot{x}$ denoting the time derivative of x. The system is subject to uncertainty and this is reflected by the dependence of matrices A, B, and C on uncertain parameter δ which is typically time varying and restricted to some bounded set

$$\delta \in \Delta \subset \mathbb{R}^q.$$

A linear control law

$$u = Ky$$

modeled by a matrix $K \in \mathbb{R}^{m \times p}$ must be designed to overcome the effect of the uncertainty while optimizing some performance criterion (e.g., pole placement, disturbance rejection, H_2 or H_∞ norm). Sometimes, a relevant performance criterion is that the control should be stabilizing for the largest possible uncertainty (measured, e.g., by some norm on Δ). In this section, for conciseness, we restrict our attention to **static output feedback** control laws, but most of the results can be extended to dynamical output feedback control laws, where the control signal u is the output of a controller (a linear system to be designed) whose input is y.

Uncertainty Models

Amongst the simplest possible uncertainty models, we can find the following:
- **Unstructured uncertainty**, also called norm-bounded uncertainty, where

$$\Delta = \{\delta \in \mathbb{R}^q : ||\delta|| \leq 1\}$$

and the given norm can be a standard vector norm or a more complicated matrix norm if δ is

interpreted as a vector obtained by stacking the column of a matrix

- **Structured uncertainty**, also called polytopic uncertainty, where

$$\Delta = \text{conv} \{\delta_i, i = 1, \ldots, N\}$$

is a polytope modeled as the convex combination of a finite number of given vertices $\delta_i \in \mathbb{R}^q, i = 1, \ldots, N$

We can find more complicated uncertainty models (e.g., combinations of the two above: see Zhou et al. 1996), but to keep the developments elementary, they are not discussed here.

Nonconvex Nonsmooth Robust Optimization

The main difficulties faced when seeking a feedback matrix K are as follows:

- **Nonconvexity**: The stability conditions are typically nonconvex in K.
- **Nondifferentiability**: The performance criterion to be optimized is typically a nondifferentiable function of K.
- **Robustness**: Stability and performance should be ensured for every possible instance of the uncertainty.

So if we are to formulate the robust control problem as an optimization problem, we should be ready to develop and use techniques from nonconvex, nondifferentiable, robust optimization.

Let us first elaborate on the first difficulty faced by optimization-based robust control, namely, the nonconvexity of the stability conditions. In continuous time, stability of a linear system $\dot{x} = Ax$ is equivalent to negativity of the spectral abscissa, which is defined as the maximum real part of the eigenvalues of A:

$$\alpha(A) = \max\{\text{Re } \lambda : \det(\lambda I_n - A) = 0, \ \lambda \in \mathbb{C}\}.$$

It turns out that the open cone of matrices $A \in \mathbb{R}^{n \times n}$ such that $\alpha(A) < 0$ is nonconvex (Ackermann 1993). This is illustrated in Fig. 1 where we represent the set of vectors $K =$

$(k_1, k_2, k_3) \in \mathbb{R}^3$ such that $k_1^2 + k_2^2 + k_3^2 < 1$ and $\alpha(A(K)) < 0$ for

$$A(K) = \begin{pmatrix} -1 & k_1 \\ k_2 & k_3 \end{pmatrix}.$$

There exist various approaches to handling nonconvexity. One possibility consists of building convex inner approximations of the stability region in the parameter space. The approximations can be polytopes, balls, ellipsoids, or more complicated convex objects described by linear matrix inequalities (LMI). The resulting stability conditions are convex, but surely conservative, in the sense that the conditions are only sufficient for stability and not necessary. Another approach to handling nonconvexity consists of formulating the stability conditions algebraically (e.g., via the Routh-Hurwitz stability criterion or its symmetric version by Hermite) and using converging hierarchies of LMI relaxations to solve the resulting nonconvex polynomial optimization problem: see, e.g., Henrion and Lasserre (2004) and Chesi (2010).

The second difficulty characteristic of optimization-based robust control is the potential nondifferentiability of the objective function. Consider for illustration one of the simplest optimization problems which consists of minimizing the spectral abscissa $\alpha(A(K))$ of a matrix $A(K)$ depending linearly on a matrix K. Such a minimization makes sense since negativity of the spectral abscissa is equivalent to system stability. Then typically, $\alpha(A(K))$ is a continuous but non-Lipschitz function of K, which means that its gradient can be unbounded locally. In Fig. 2, we plot the spectral abscissa $\alpha(A(K))$ for

$$A(K) = \begin{pmatrix} 0 & 1 \\ K & -K \end{pmatrix}$$

and $K \in \mathbb{R}$. The function is non-Lipschitz at $K = 0$, at which the global minimum $\alpha(A(0)) = 0$ is achieved. Nonconvexity of the function is also apparent in this example. The lack of convexity and smoothness of the spectral abscissa and other similar performance criteria renders optimization of such functions particularly difficult (Burke

**Optimization Based Robust Control, Fig. 1** A nonconvex ball of stable matrices
Optimization Based Robust Control, Fig. 2 The spectral abscissa is typically nonconvex and nonsmooth
et al. 2001, 2006b). In Fig. 3, we represent graphs of the spectral abscissa (with flipped vertical axis for better visualization) of some small-size matrices depending on two real parameters, with randomly generated parametrization. We observe the typical nonconvexity and lack of smoothness around local and global optima.

The third difficulty for optimization-based robust control is the uncertainty. As explained above, optimization of a performance criterion with respect to controller parameters is already a potentially difficult problem for a nominal system (i.e., when the uncertainty parameter is equal to zero). This becomes even more difficult

Optimization Based Robust Control, Fig. 3 The graph of the negative spectral abscissa for some randomly generated matrix parametrizations

when this optimization must be carried out for all possible instances of the uncertainty δ in Δ. This is where the above assumption that the uncertainty set Δ has a simple description proves useful. If the uncertainty δ is unstructured and not time varying, then it can be handled with the complex stability radius (Ackermann 1993), the pseudospectral abscissa (Trefethen and Embree 2005), or via an H_∞ norm constraint (Zhou et al. 1996). If the uncertainty δ is structured, then we can try to optimize a performance criterion at every vertex in the polytopic description (which is a relaxation of the problem of stabilizing the whole polytope). An example is the problem of simultaneous stabilization, where a controller K must be found such that the maximum spectral abscissa of several matrices $A_i(K), i = 1, \ldots, N$ is negative (Blondel 1994). Finally, if the uncertainty δ is time varying, then performance and stability guarantees can still be achieved with the help of Lyapunov certificates or potentially conservative convex LMI conditions: see, e.g., Boyd et al. (1994) and Scherer et al. (1997).

A unified approach to addressing conflicting performance criteria and uncertainty consists of searching for locally optimal solutions of a nonsmooth optimization problem that is built to incorporate minimization objectives and constraints for multiple plants. This is called (linear robust) **multiobjective control**, and formally, it can be expressed as the following optimization problem

$$\min_K \max_{i=1,\ldots,N}\{g_i(K) : \beta_i = \infty\}$$
$$\text{s.t. } g_i(K) \leq \beta_i, i = 1, \ldots, N,$$

where each $g_i(K)$ is a function of the closed-loop matrix $A_i(K)$ (e.g., a spectral abscissa or an H_∞ norm) and the scalars β_i are given and such that if $\beta_i = \infty$ for some i, then g_i appears in the objective function and not in a constraint: see Gumussoy et al. (2009) for details. In the above problem, the objective function, a maximum of nonsmooth and nonconvex functions, is typically also nonsmooth and nonconvex. Moreover, without loss of generality,

we can easily impose a sparsity pattern on controller matrix K to account for structural constraints (e.g., a low-order decentralized controller).

Software Packages

Algorithms for **nonconvex nonsmooth optimization** have been developed and interfaced for linear robust multiobjective control in the public domain Matlab package HIFOO released in Burke et al. (2006a) and based on the theory described in Burke et al. (2006b). In 2011, The MathWorks released HINFSTRUCT, a commercial implementation of these techniques based on the theory described in Apkarian and Noll (2006).

Abstract

Structured output feedback controller synthesis is an exciting new concept in modern control design, which bridges between theory and practice insofar as it allows for the first time to apply sophisticated mathematical design paradigms like H_∞ or H_2 control within control architectures preferred by practitioners. The new approach to structured H_∞ control, developed during the past decade, is rooted in a change of paradigm in the synthesis algorithms. Structured design may no longer be based on solving algebraic Riccati equations or matrix inequalities. Instead, optimization-based design techniques are required. In this essay we indicate why structured controller synthesis is central in modern control engineering. We explain why non-smooth optimization techniques are needed to compute structured control laws, and we point to software tools which enable practitioners to use these new tools in high-technology applications.

Introduction

In the modern high-technology field of control, engineers usually face a large variety of concurring design specifications such as noise or gain attenuation in prescribed frequency bands, damping, decoupling, constraints on settling or rise time, and much else. In addition, as plant models are generally only approximations of the true system dynamics, control laws have to be robust with respect to uncertainty in physical parameters or with regard to un-modeled high-frequency phenomena. Not surprisingly, such a plethora of constraints present a major challenge for controller tuning, not only due to the ever-growing number of such constraints but also because of their very different provenience.

The dramatic increase in plant complexity is exacerbated by the desire that regulators should be as simple as possible, easy to understand and to tune by practitioners, convenient to hardware implement, and generally available at low cost. Such practical constraints explain the limited use of black-box controllers, and they are the driving force for the implementation of *structured* control architectures, as well as for the tendency to replace hand-tuning methods by rigorous algorithmic optimization tools.

Structured Controllers

Before addressing specific optimization techniques, we introduce some basic terminology for control design problems with structured controllers. A state-space description of the given P used for design is given as

$$P : \begin{cases} \dot{x}_P = A x_P + B_1 w + B_2 u \\ z = C_1 x_P + D_{11} w + D_{12} u \\ y = C_2 x_P + D_{21} w + D_{22} u \end{cases} \quad (1)$$

where A, B_1,... are real matrices of appropriate dimensions, $x_P \in \mathbb{R}^{n_P}$ is the state, $u \in \mathbb{R}^{n_u}$ the control, $y \in \mathbb{R}^{n_y}$ the measured output, $w \in \mathbb{R}^{n_w}$ the exogenous input, and $z \in \mathbb{R}^{n_z}$ the regulated output. Similarly, the sought output feedback controller K is described as

$$K : \begin{cases} \dot{x}_K = A_K x_K + B_K y \\ u = C_K x_K + D_K y \end{cases} \quad (2)$$

with $x_K \in \mathbb{R}^{n_K}$ and is called *structured* if the (real) matrices A_K, B_K, C_K, D_K depend smoothly on a design parameter $\mathbf{x} \in \mathbb{R}^n$, referred to as the vector of tunable parameters. Formally, we have differentiable mappings

$$A_K = A_K(\mathbf{x}), B_K = B_K(\mathbf{x}), C_K = C_K(\mathbf{x}),$$
$$D_K = D_K(\mathbf{x}),$$

and we abbreviate these by the notation $K(\mathbf{x})$ for short to emphasize that the controller is structured with $\mathbf{x}$ as tunable elements.

A structured controller synthesis problem is then an optimization problem of the form

$$\begin{aligned} & \text{minimize } \|T_{wz}(P, K(\mathbf{x}))\| \\ & \text{subject to } K(\mathbf{x}) \text{ closed-loop stabilizing} \quad (3) \\ & \qquad K(\mathbf{x}) \text{ structured, } \mathbf{x} \in \mathbb{R}^n \end{aligned}$$

where $T_{wz}(P, K) = \mathcal{F}_\ell(P, K)$ is the lower feedback connection of (1) with (2) as in Fig. 1 (left), also called the linear fractional transformation (Varga and Looye 1999). The norm $\|\cdot\|$ stands for the H_∞ norm, the H_2 norm, or any other system norm, while the optimization variable $\mathbf{x} \in \mathbb{R}^n$ regroups the tunable parameters in the design.

Standard examples of structured controllers $K(\mathbf{x})$ include realizable PIDs and observer-based, reduced-order, or decentralized controllers, which in state space are expressed as

$$\left[\begin{array}{cc|c} 0 & 0 & 1 \\ 0 & -1/\tau & -k_D/\tau \\ \hline k_I & 1/\tau & k_P + k_D/\tau \end{array} \right], \left[\begin{array}{c|c} A - B_2 K_c - K_f C_2 & K_f \\ \hline -K_c & 0 \end{array} \right],$$

$$\left[\begin{array}{c|c} A_K & B_K \\ \hline C_K & D_K \end{array} \right], \left[\begin{array}{c|c} \operatorname*{diag}_{i=1}^{q} A_{Ki} & \operatorname*{diag}_{i=1}^{q} B_{Ki} \\ \hline \operatorname*{diag}_{i=1}^{q} C_{Ki} & \operatorname*{diag}_{i=1}^{q} D_{Ki} \end{array} \right].$$
Optimization-Based Control Design Techniques and Tools, Fig. 1 Black-box full-order controller K on the *left*, structured 2-DOF control architecture with $K =$ block-diag(K_1, K_2) on the *right*

Optimization-Based Control Design Techniques and Tools, Fig. 2 Synthesis of $K =$ block-diag$(K_1, \ldots, K_N)$ against multiple requirements or models $P^{(1)}, \ldots, P^{(M)}$. Each $K_i(\mathbf{x})$ can be structured
In the case of a PID, the tunable parameters are $\mathbf{x} = (\tau, k_P, k_I, k_D)$, for observer-based controllers $\mathbf{x}$ regroups the estimator and state-feedback gains (K_f, K_c), for reduced order controllers $n_K < n_P$ the tunable parameters $\mathbf{x}$ are the $n_K^2 + n_K n_y + n_K n_u + n_y n_u$ unknown entries in (A_K, B_K, C_K, D_K), and in the decentralized form $\mathbf{x}$ regroups the unknown entries in $A_{K1}, \ldots, D_{Kq}$. In contrast, full-order controllers have the maximum number $N = n_P^2 + n_P n_y + n_P n_u + n_y n_u$ of degrees of freedom and are referred to as unstructured or as *black-box* controllers.

More sophisticated controller structures $K(\mathbf{x})$ arise from architectures like, for instance, a 2-DOF control arrangement with feedback block K_2 and a set-point filter K_1 as in Fig. 1 (right). Suppose K_1 is the 1st-order filter $K_1(s) = a/(s + a)$ and K_2 the PI feedback $K_2(s) = k_P + k_I/s$. Then the transfer T_{ry} from r to y can be represented as the feedback connection of P and $K(\mathbf{x})$ with

$$P := \left[\begin{array}{c|ccc} A & 0 & 0 & B \\ \hline C & 0 & 0 & D \\ 0 & I & 0 & 0 \\ -C & 0 & I & -D \end{array} \right], K(\mathbf{x}) := \left[\begin{array}{cc} K_1(s) & 0 \\ 0 & K_2(s) \end{array} \right],$$

where $K(\mathbf{x})$ takes a typical block-diagonal structure featuring the tunable elements $\mathbf{x} = (a, k_P, k_I)$.

In much the same way, arbitrary multi-loop interconnections of fixed-model elements with tunable controller blocks $K_i(\mathbf{x})$ can be rearranged as in Fig. 2 so that $K(\mathbf{x})$ captures all tunable blocks in a decentralized structure general enough to cover most engineering applications.

The structure concept is equally useful to deal with the second central challenge in control design: *system uncertainty*. The latter may be handled with μ-synthesis techniques (Stein and Doyle 1991) if a parametric uncertain model is available. A less ambitious but often more practical alternative consists in optimizing the structured controller $K(\mathbf{x})$ against a finite set of plants $P^{(1)}, \ldots, P^{(M)}$ representing model variations due to uncertainty, aging, sensor and actuator breakdown, and un-modeled dynamics, in tandem with the robustness and performance specifications. This is again formally covered by Fig. 2 and leads to a multi-objective constrained optimization problem of the form

$$\text{minimize} \quad f(\mathbf{x}) = \max_{k \in \text{SOFT}, i \in I_k} \|T_{w_i z_i}^{(k)}(K(\mathbf{x}))\|$$

subject to $g(\mathbf{x}) = \max\limits_{k \in \text{HARD}, j \in J_k} \|T^{(k)}_{w_j z_j}(K(\mathbf{x}))\| \leq 1$

$$K(\mathbf{x}) \text{ structured and stabilizing}$$

$$\mathbf{x} \in \mathbb{R}^n \qquad (4)$$

where $T^{(k)}_{w_i z_i}$ denotes the ith closed-loop robustness or performance channel $w_i \rightarrow z_i$ for the kth plant model $P^{(k)}(s)$. The rationale of (4) is to minimize the worst-case cost of the soft constraints $\|T^{(k)}_{w_i z_i}\|$, $k \in \text{SOFT}$ while enforcing the hard constraints $\|T^{(k)}_{w_j z_j}\| \leq 1$, $k \in \text{HARD}$. Note that in the mathematical programming terminology, soft and hard constraints are classically referred to as objectives and constraints. The terms soft and hard point to the fact that hard constraints prevail over soft ones and that meeting hard constraints for solution candidates is mandatory.

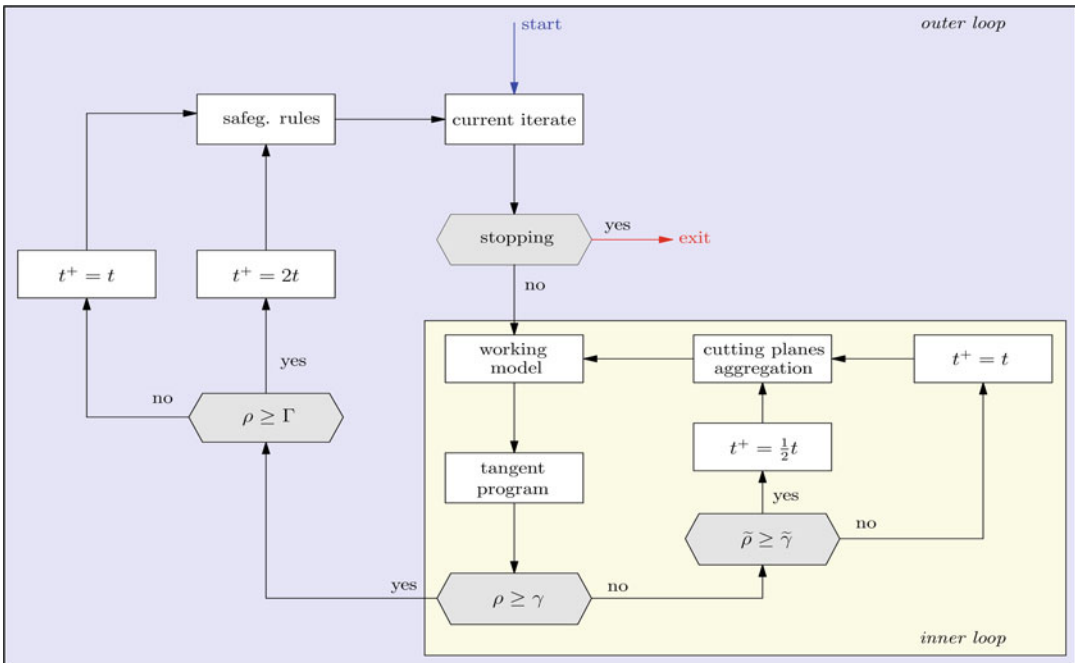
Optimization Techniques Over the Years

During the late 1990s, the necessity to develop design techniques for structured regulators $K(\mathbf{x})$ was recognized (Fares et al. 2001), and the limitations of synthesis methods based on algebraic Riccati equations (AREs) or linear matrix inequalities (LMIs) became evident, as these techniques can only provide black-box controllers. The lack of appropriate synthesis techniques for structured $K(\mathbf{x})$ led to the unfortunate situation, where sophisticated approaches like the H_∞ paradigm developed by academia since the 1980s could not be brought to work for the design of those controller structures $K(\mathbf{x})$ preferred by practitioners. Design engineers had to continue to rely on heuristic and ad hoc tuning techniques, with only limited scope and reliability. As an example, post-processing to reduce a black-box controller to a practical size is prone to failure. It may at best be considered a fill-in for a rigorous design method which directly computes a reduced-order controller. Similarly, hand-tuning of the parameters $\mathbf{x}$ remains a puzzling task because of the loop interactions and fails as soon as complexity increases.

In the late 1990s and early 2000s, a change of methods was observed. Structured H_2- and H_∞-synthesis problems (3) were addressed by bilinear matrix inequality (BMI) optimization, which used local optimization techniques based on the augmented Lagrangian method (Fares et al. 2001; Noll et al. 2002; Kocvara and Stingl 2003), sequential semidefinite programming methods (Fares et al. 2002; Apkarian et al. 2003), and non-smooth methods for BMIs (Noll et al. 2009; Lemaréchal and Oustry 2000). However, these techniques were based on the bounded real lemma or similar matrix inequalities and were therefore of limited success due to the presence of Lyapunov variables, i.e., matrix-valued unknowns, whose dimension grows quadratically in $n_P + n_K$ and represents the bottleneck of that approach.

The epoch-making change occurs with the introduction of non-smooth optimization techniques (Noll and Apkarian 2005; Apkarian and Noll 2006b,c, 2007) to programs (3) and (4). Today non-smooth methods have superseded matrix inequality-based techniques and may be considered the state of the art as far as realistic applications are concerned. The transition took almost a decade.

Alternative control-related local optimization techniques and heuristics include the gradient sampling technique of Burke et al. (2005), derivative-free optimization discussed in Kolda et al. (2003) and Apkarian and Noll (2006a) and particle swarm optimization; see Oi et al. (2008) and references therein and also evolutionary computation techniques (Lieslehto 2001). The last three classes do not exploit derivative information and rely on function evaluations only. They are therefore applicable to a broad variety of problems including those where function values arise from complex numerical simulations. The combinatorial nature of these techniques, however, limits their use to small problems with a few tens of variable. More significantly, these methods often lack a solid convergence theory. In contrast, as we have demonstrated over recent years (Apkarian and Noll 2006b; Noll et al. 2008),

specialized non-smooth techniques are highly efficient in practice, are based on a sophisticated convergence theory, are capable of solving medium-size problems in a matter of seconds, and are still operational for large-size problems with several hundreds of states.


Non-smooth Optimization Techniques

The benefit of the non-smooth casts (3) and (4) lies in the possibility to avoid searching for Lyapunov variables, a major advantage as their number $(n_P + n_K)^2/2$ usually largely dominates n, the number of true decision parameters $\mathbf{x}$. Lyapunov variables do still occur implicitly in the function evaluation procedures, but this has no harmful effect for systems up to several hundred states. In abstract terms, a non-smooth optimization program has the form

$$\begin{aligned} \text{minimize} \quad & f(\mathbf{x}) \\ \text{subject to} \quad & g(\mathbf{x}) \leq 0 \\ & \mathbf{x} \in \mathbb{R}^n \end{aligned} \quad (5)$$

where $f, g : \mathbb{R}^n \rightarrow \mathbb{R}$ are locally Lipschitz functions and are easily identified from the cast in (4).

In the realm of convex optimization, non-smooth programs are conveniently addressed by so-called bundle methods, introduced in the late 1970s by Lemaréchal (1975). Bundle methods are used to solve difficult problems in integer programming or in stochastic optimization via Lagrangian relaxation. Extensions of the bundling technique to non-convex problems like (3) or (4) were first developed in Apkarian and Noll (2006b,c, 2007), Apkarian et al. (2008), Noll et al. (2009), and, in more abstract form, Noll et al. (2008).

Figure 3 shows a schematic view of a non-convex bundle method consisting of a descent-step generating inner loop (yellow block) comparable to a line search in smooth optimization, embedded into the outer loop

Optimization-Based Control Design Techniques and Tools, Fig. 3 Flowchart of proximity control bundle algorithm

(blue box), where serious iterates are processed, stopping criteria are applied, and the model tradition is assured. Serious steps or iterates refer to steps accepted in a line search, while null steps are unsuccessful steps visited during the search. By model tradition, we mean continuity of the model between (serious) iterates x^j and x^{j+1} by recycling some of the older planes used at counter j into the new working model at $j + 1$. This avoids starting the first inner loop $k = 1$ at $j + 1$ from scratch and therefore saves time.

At the core of the interaction between inner and outer loop is the management of the proximity control parameter τ, which governs the stepsize $\|\mathbf{x} - \mathbf{y}^k\|$ between trial steps $\mathbf{y}^k$ at the current serious iterate $\mathbf{x}$. Similar to the management of a trust region radius or of the stepsize in a line search, proximity control allows to force shorter trial steps if agreement of the local model with the true objective function is poor and allows larger steps if agreement is satisfactory.

Oracle-based bundle methods traditionally assure global convergence in the sense of subsequences under the sole hypothesis that for every trial point $\mathbf{x}$, the function value $f(\mathbf{x})$ and a Clarke subgradient $\phi \in \partial f(\mathbf{x})$ are provided. In automatic control applications, it is as a rule possible to provide more specific information, which may be exploited to speed up convergence.

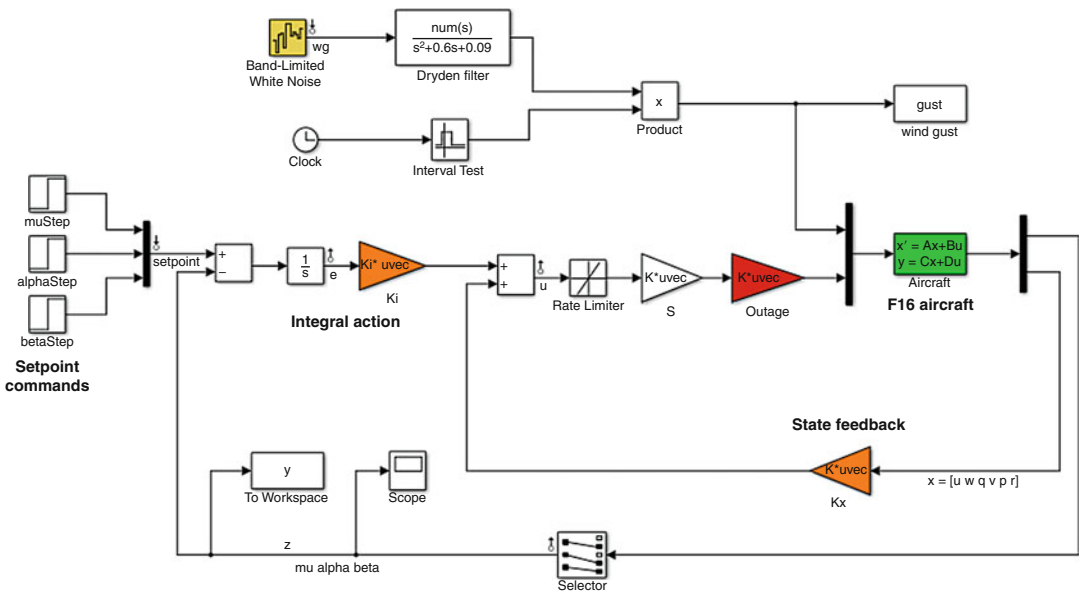
Computing function value and gradients of the H_2 norm $f(\mathbf{x}) = \|T_{wz}(P, K(\mathbf{x}))\|_2$ requires essentially the solution of two Lyapunov equations of size $n_P + n_K$ (see Apkarian et al. 2007; Rautert and Sachs 1997). For the H_∞ norm, $f(\mathbf{x}) = \|T_{wz}(P, K(\mathbf{x}))\|_\infty$, function evaluation is based on the Hamiltonian algorithm of Benner et al. (2012) and Boyd et al. (1989). The Hamiltonian matrix is of size $n_P + n_K$ so that function evaluations may be costly for very large plant state dimension ($n_P > 500$), even though the number of outer loop iterations of the bundle algorithm is not affected by a large n_P and generally relates to n, the dimension of $\mathbf{x}$. The additional cost for subgradient computation for large n_P is relatively cheap as it relies on linear algebra (Apkarian and Noll 2006b).

Computational Tools

The novel non-smooth optimization methods became available to the engineering community since 2010 via the MATLAB Robust Control Toolbox (Robust Control Toolbox 4.2 2012; Gahinet and Apkarian 2011). Routines HINFSTRUCT, LOOPTUNE, and SYSTUNE are versatile enough to define and combine tunable blocks $K_i(\mathbf{x})$, to build and aggregate design requirements $T_{wz}^{(k)}$ of different nature, and to provide suitable validation tools. Their implementation was carried out in cooperation with P. Gahinet (MathWorks). These routines further exploit the structure of problem (4) to enhance efficiency (see Apkarian and Noll 2006b, 2007).

It should be mentioned that design problems with multiple hard constraints are inherently complex. It is well known that even simultaneous stabilization of more than two plants $P^{(j)}$ with a structured control law $K(\mathbf{x})$ is NP-complete so that exhaustive methods are expected to fail even for small to medium problems. The principled decision made in Apkarian and Noll (2006b) and reflected in the MATLAB routines is to rely on local optimization techniques instead. This leads to weaker convergence certificates but has the advantage to work successfully in practice. In the same vein, in (4) it is preferable to rely on a mixture of soft and hard requirements, for instance, by the use of exact penalty functions (Noll and Apkarian 2005). Key features implemented in the mentioned MATLAB routines are discussed in Apkarian (2013), Gahinet and Apkarian (2011), and Apkarian and Noll (2007).

Design Example

Design of a feedback regulator is an interactive process, in which tools like SYSTUNE, LOOPTUNE, or HINFSTRUCT support the designer in various ways. In this section we illustrate their enormous potential by solving a multi-model, fixed-structure reliable flight control design problem.


Optimization-Based Control Design Techniques and Tools, Fig. 4 Synthesis interconnection for reliable control

Optimization-Based Control Design Techniques and Tools, Table 1 Outage scenarios where 0 stands for failure

Outage cases	Diagonal of outage gain				
Nominal mode	1	1	1	1	1
Right elevator outage	0	1	1	1	1
Left elevator outage	1	0	1	1	1
Right aileron outage	1	1	0	1	1
Left aileron outage	1	1	1	0	1
Left elevator and right aileron outage	1	0	0	1	1
Right elevator and right aileron outage	0	1	0	1	1
Right elevator and left aileron outage	0	1	1	0	1
Left elevator and left aileron outage	1	0	1	0	1

In reliable flight control, one has to maintain stability and adequate performance not only in nominal operation but also in various scenarios where the aircraft undergoes outages in elevator and aileron actuators. In particular, wind gusts must be alleviated in all outage scenarios to maintain safety. Variants of this problem are addressed in Liao et al. (2002).

The open loop F16 aircraft in the scheme of Fig. 4 has six states, the body velocities u, v, w and pitch, roll, and yaw rates q, p, r. The state is available for control as is the flight-path bank angle rate μ (deg/s), the angle of attack α (deg), and the sideslip angle β (deg). Control inputs are the left and right elevator, left and right aileron,

and rudder deflections (deg). The elevators are grouped symmetrically to generate the angle of attack. The ailerons are grouped antisymmetrically to generate roll motion. This leads to three control actions as shown in Fig. 4. The controller consists of two blocks, a 3×6 state-feedback gain matrix K_x in the inner loop and a 3×3 integral gain matrix K_i in the outer loop, which leads to a total of $27 = \dim \mathbf{x}$ parameters to tune.

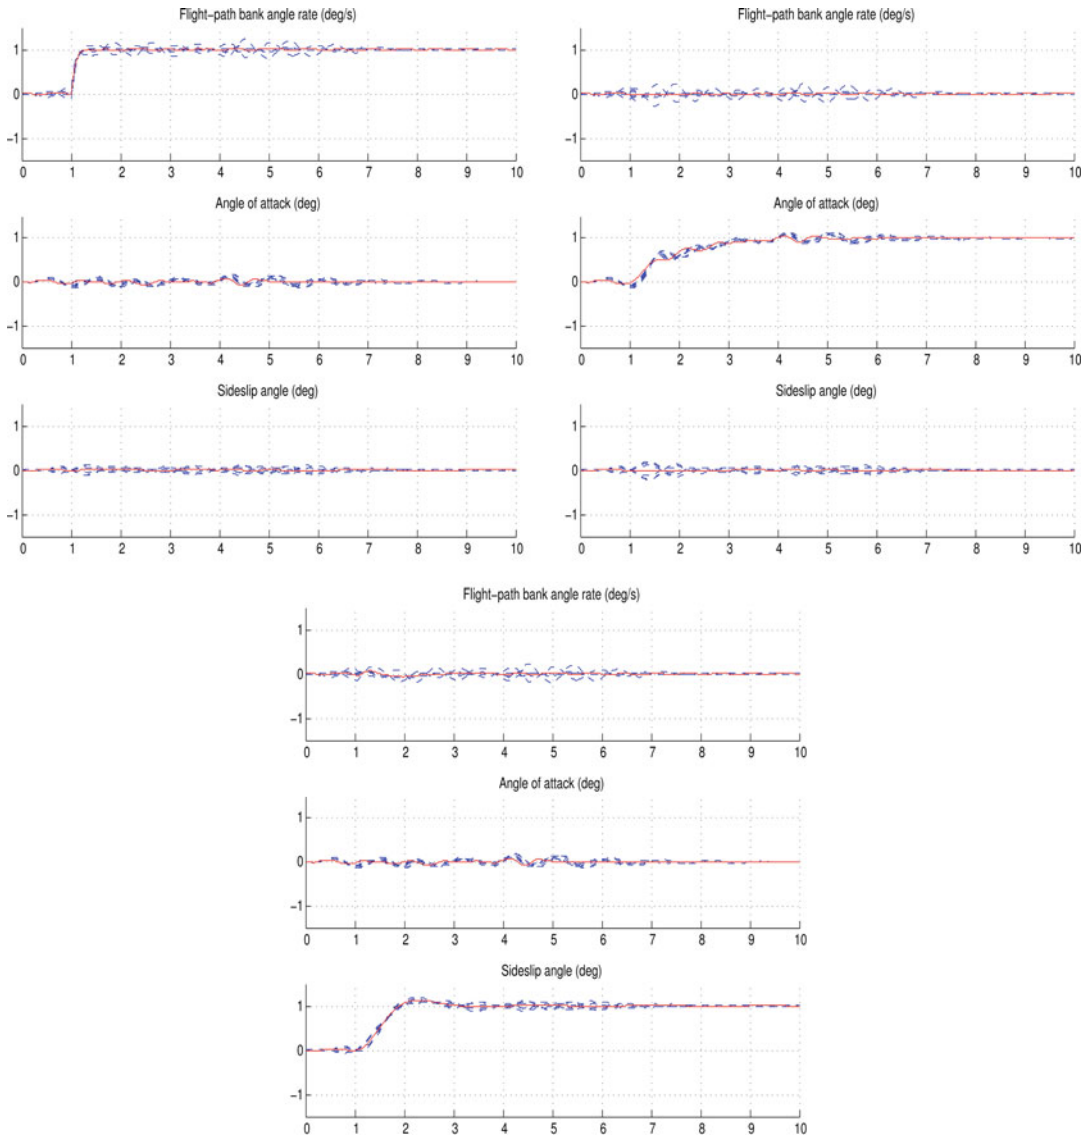
In addition to nominal operation, we consider eight outage scenarios shown in Table 1.

The different models associated with the outage scenarios are readily obtained by premultiplication of the aircraft control input by a diagonal matrix built from the rows in Table 1.
Optimization-Based Control Design Techniques and Tools, Fig. 5 Responses to step changes in μ, α, and β for nominal design

The design requirements are as follows:
- Good tracking performance in μ, α, and β with adequate decoupling of the three axes.
- Adequate rejection of wind gusts of 5 m/s.
- Maintain stability and acceptable performance in the face of actuator outage.

Tracking is addressed by an LQG cost (Maciejowski 1989), which penalizes integrated tracking error e and control effort u via

$$J = \lim_{T \to \infty} E \left(\frac{1}{T} \int_0^T \|W_e e\|^2 + \|W_u u\|^2 dt \right). \tag{6}$$

Diagonal weights W_e and W_u provide tuning knobs for trade-off between responsiveness, control effort, and balancing of the three channels. We use $W_e = \text{diag}(20, 30, 20)$, $W_u = I_3$ for normal operation and $W_e = \text{diag}(8, 12, 8)$, $W_u = I_3$ for outage conditions. Model-dependent weights


Optimization-Based Control Design Techniques and Tools, Fig. 6 Responses to step changes in μ, α, and β for fault-tolerant design

allow to express the fact that nominal operation prevails over failure cases. Weights for failure cases are used to achieve limited deterioration of performance or of gust alleviation under deflection surface breakdown.

The second requirement, wind gust alleviation, is treated as a hard constraint limiting the variance of the error signal e in response to white noise w_g driving the Dryden wind gust model.

In particular, the variance of e is limited to 0.01 for normal operation and to 0.03 for the outage scenarios.

With the notation of section "Non-smooth Optimization Techniques," the functions $f(\mathbf{x})$ and $g(\mathbf{x})$ in (5) are $f(\mathbf{x}) := \max_{k=1,\dots,9} \|T_{rz}^{(k)}(\mathbf{x})\|_2$ and $g(\mathbf{x}) := \max_{k=1,\dots,9} \|T_{w_g e}^{(k)}(\mathbf{x})\|_2$, where r denotes the set-point inputs in μ, α, and β. The regulated output z is

$$z^T := \left[(W_e^{1/2} e)^T \ (W_u^{1/2} u)^T \right]^T,$$

with $\mathbf{x} = (\text{vec}(K_i), \text{vec}(K_x)) \in \mathbb{R}^{27}$. Soft constraints are the square roots of J in (6) with appropriate weightings W_e and W_u, hard constraints the RMS values of e, suitably weighted to reflect variance bounds of 0.01 and 0.03. These requirements are covered by the `Variance` and `WeightedVariance` options in Robust Control Toolbox 4.2 (2012).

With this setup, we tuned the controller gains K_i and K_x for the nominal scenario only (*nominal design*) and for all nine scenarios (*fault-tolerant design*). The responses to setpoint changes in μ, α, and β with a gust speed of 5 m/s are shown in Fig. 5 for the nominal design and in Fig. 6 for the fault-tolerant design. As expected, nominal responses are good but notably deteriorate when faced with outages. In contrast, the fault-tolerant controller maintains acceptable performance in outage situations. Optimal performance (square root of LQG cost J in (6)) for the fault-tolerant design is only slightly worse than for the nominal design (26 vs. 23). The non-smooth program (5) was solved with `SYSTUNE`, and the fault-tolerant design (9 models, 11 states, 27 parameters) took 30 s on Mac OS X with 2.66 GHz Intel Core i7 and 8 GB RAM. The reader is referred to Robust Control Toolbox 4.2 (2012) or higher versions, for further examples, and additional details.

Future Directions

From an application viewpoint, non-smooth optimization techniques for control system design and tuning will become one of the standard techniques in the engineer's toolkit. They are currently studied in major European aerospace industries.

Future directions may include:

- Extension of these techniques to gain scheduling in order to handle larger operating domains.
- Application of the available tools to integrated system/control when both system physical characteristics and controller elements are optimized to achieve higher performance. Application to fault detection and isolation may also reveal as an interesting vein.

Option Games: The Interface Between Optimal Stopping and Game Theory

Benoit Chevalier-Roignant[1] and Lenos Trigeorgis[2]

[1]Oliver Wyman, Munich, Germany

[2]University of Cyprus, Nicosia, Cyprus

Abstract

Managers can stake a claim by committing to capital investments today that can influence their rivals' behavior or take a "wait-and-see" or step-by-step approach to avoid possible adverse market consequences tomorrow. At the core of this corporate dilemma lies the classic trade-off between commitment and flexibility. This trade-off calls for a careful balancing of the merits of flexibility against those of commitment. This balancing is captured by option games.

Keywords

Game theory; Option games; Optimal stopping; Real options

Introduction

The global competitive environment has become increasingly more challenging as modern economies undergo unprecedented changes in the midst of the global economic turmoil. Real-world dilemmas corporate managers face today are driven by the interplay among strategic and market uncertainty. The tech industry has evolved most rapidly, putting companies unable to respond to market developments and technological breakthroughs at severe disadvantage. Corporate management's plans and how they implement their strategy will likely determine whether the firm will survive and be successful in the marketplace or become extinct.

Formulating the right strategy in the right competitive environment at the right time is a nontrivial task. Whether to invest in a new technology, a new product or enter a new market is a strategic decision of immense importance. Corporate management must assess strategic options with proper analytical tools that can help determine whether to commit to a particular strategic path, given scarce or costly resources, or whether to stay flexible. Oftentimes, firms need to position themselves flexibly to capitalize on future opportunities as they emerge, while limiting potential losses arising from adverse future circumstances. In many cases, corporate managers find themselves in need to revise their decision plans in view of actual market developments when facing an uncertain future; they can then decide to undertake only those projects with sufficiently high prospects in the future to justify commitment at that time. This needs to be balanced with the need to make irreversible strategic commitments to seize first-mover advantage presenting rivals with a *fait accompli* to which they have no choice but adapt.

Capital Budgeting Ignoring Strategic Interactions

Net Present Value

Prevailing management approaches simplify matters and often lead to investment decisions that are detrimental to the firm's long-term well-being. Suppose a firm's future cash flow at time t is given by a random variable X_t. Cash flows then evolve as a geometric Brownian motion

$$dX_t = gX_t dt + \sigma X_t dB_t \text{ and } X_0 \equiv x$$

with drift parameter g and volatility σ. The Brownian motion $(B_t; t \geq 0)$ captures exogenous market uncertainty. The standard criterion used in corporate finance is based on discounted cash flows (DCF) or net present value (NPV). This consists in assessing the current value of a project by discounting the expected future cash flows $E[X_t]$ at a constant discount rate, r. Management supposedly creates shareholder value by under-

taking projects with positive NPV, i.e., projects for which the present value of cash flows, $v(x) = \int_0^\infty e^{-rt} E[X_t] dt$, exceeds the necessary investment cost, I. In the present case, the firm will invest under the zero-NPV criterion if

$$\frac{x}{r-g} \geq I \qquad (1)$$

This traditional criterion views investment opportunities as now-or-never decisions under passive management. However, this precludes the possibility to adjust future decisions in case the market develops off the expected path. While market uncertainty is factored in through the discount rate, the flexibility management has is typically not properly accounted for.

Real Options Analysis

It has become standard practice in finance and strategy to interpret real investment opportunities as being analogous to financial options. This view is well accepted among academics and practitioners alike and is at the core of real options analysis (ROA). ROA is an extension of option-pricing theory to real investment situations (Myers 1977; Trigeorgis 1996). This approach effectively allows one to capture the dynamic nature of decision-making since it factors in management's flexibility to revise and adapt its decision in the face of market uncertainty. ROA allows managers with flexibility to adapt to actual market developments as uncertainty gets resolved. Managers may, for example, delay the start (or closure) of a project depending on its prospects. This approach leverages on optimal stopping theory (e.g., see Bensoussan and Lions 1982; Dixit and Pindyck 1994) and is considered to be more reflective of real decision-making than traditional methods. In the case the firm can delay the decision to invest, for example, the problem is one of optimal stopping:

$$V(x) = \max_T E[e^{-rT}(v(X_T) - I)]$$

by ROA, the discount rate r is the risk-free interest (Dixit and Pindyck 1994; Trigeorgis 1996). The time of managerial action, T, is

now a strategic decision variable random by nature as the decision maker faces an uncertain environment. This problem has an analytical solution characterized by a threshold policy, say a trigger $\bar{X}$, given by

$$\frac{\bar{X}}{r-g} = \frac{b}{b-1}I \qquad (2)$$

where b is the positive root of a quadratic function (e.g., see Dixit and Pindyck 1994) and $b/(b-1) > 1$. When decisions are costly or difficult to reverse, corporate managers would be more cautious and careful to make decisions. A firm should not always commit immediately – even if the NPV criterion (1) indicates so – but wait until the gross project value is sufficiently positive to cover the investment cost I by a factor larger than one, as expressed in (2). Investing prematurely may destroy shareholder value. Real options may justify sometimes undertaking projects with negative (static) net present value if it creates a platform for growth options or delaying projects with positive NPV.

Accounting for Strategic Interactions in Capital Budgeting

Strategic Uncertainty

As natural monopolies have lost their secular well-protected positions owing to market liberalization in the European Union and elsewhere across the globe, strategic interdependencies have become new key challenge for managers. At the same time sectors traditionally populated by multiple firms have undergone significant consolidation, often resulting in oligopolistic situations with a reduced number of players. The ongoing economic crisis has amplified these consolidation pressures. These two ongoing phenomena – liberalization and consolidation – have put high on the corporate agenda the assessment of strategic options under competition. Standard real options analysis often examines investment decisions as if the option holder has a proprietary right to exercise. This perspective may not be realistic in the new oligopolistic environment as several

firms may share the right to a related investment opportunity in the industry.

Game Theory

In oligopolistic industries, firms often have difficulty predicting how rivals will behave and make decisions based on beliefs about their likely behavior. A theory that helps characterize beliefs and form predictions about which strategies opponents will follow is helpful in analyzing such oligopolistic situations. Game theory has traditionally been used to frame strategic interactions arising in conflict situations involving parties with different objectives or interests. It attempts to model behavior in strategic situations or games in which one party's success in making choices depends on the choices of other players through influencing one another's welfare. Game theory adopts a different perspective on optimization, as the focus is on the formation of beliefs about how rivals' optimal strategies. Finance theory has been primarily concerned with "moves by nature," while game theory focuses on "optimization problems" involving multiple players. To solve a game, one needs to reduce a complex multiplayer problem into a simpler structure that captures the essence of the conflict situation. One can then derive useful predictions about how rivals are likely to react in a given situation. Game theory helped reshape microeconomics by providing analytical foundations for the study of market behavior and has been at the foundation of the Nobel prize winning research field of industrial organization.

Dynamic game theory (see, e.g., Basar and Olsder 1999) addresses problems in which several parties are in repeated interaction. Strategic management approaches based on dynamic economic theory can provide a richer foundation for understanding developments and competitive reactions within an industry. As firm competitiveness involves interactions among several players (rivals, suppliers or clients), game theoretic analysis brings important insights into strategic management in addressing such issues as first- and second-mover advantages, firm entry and exit decisions, strategic commitment, reputation, signaling, and other informational

O

effects. A key lesson is that, when firms react to one another, it may sometimes be appropriate for one firm to take an aggressive stance in expectation that rivals will back off. Dynamic industrial organization includes the analysis of "games of timing" such as preemption games or war of attrition, whereby firms decide on appropriate investment timing under rivalry.

Option Games

The earlier optimal stopping problem falls in the category of "games of timing" when a firm's entry decision influences another firm's market strategy. Option games are most suitable to help model situations where a firm that has a real option to (dis)invest faces rivalry. Here, the problem consists in finding a Nash equilibrium solution for the two-player equivalent of the above optimal stopping problem. This solution must also satisfy certain dynamic consistency criteria. For sequential investments, the follower is faced with a single-agent optimal investment timing problem; it will thus enter if the gross project value exceeds the investment cost by a sufficient factor. A firm entering the market early on, i.e., a leader, earns temporary monopoly rents as long as demand remains below the follower's entry threshold. Following the follower's entry, the firms act as a duopoly. As long as the leader's value exceeds the follower's, there is an incentive for one firm to invest, but not necessarily for both of them, leading to a "coordination problem." The competitive pressure will dissipate away the leader's first-mover advantage, leading to a market entry point that is not socially optimal and to rent dissipation. Unfortunately, the multiplayer problem does not involve a simple analytical solution, since at each point a duopolist firm might end up in any of four distinct situations (two-by-two matrix) depending on the rival's entry decision. Option games indicate in each situation which driving force (commitment vs. flexibility) prevails and whether to go ahead with the investment or wait and see. Main drivers of the prevailing market

equilibrium include the riskiness of the venture, σ, the magnitude of the first-mover advantage and the exclusive or shared ability to reap the benefits of the investment vis-à-vis rivals. When firms can grasp a large first-mover advantage from investing early but cannot differentiate themselves sufficiently from each other, they may be tempted to wage a preemptive war, investing prematurely at an early market stage that actually kills option value. If firms are more on an equal footing but do not see much benefit from investing early, they may prefer to wait and invest (jointly) at a later stage when the future market is sufficiently mature. If, however, one firm has a comparative cost advantage that dominates (e.g., a radical or drastic technological superiority) its rival industry, participants may prefer a consensual leader-follower investment arrangement involving less option value destruction.

Conclusions

Corporate management's strategic tool kit should provide clearer guidance on whether to pursue a wait-and-see stance in the face of uncertain market developments or jump on the first-mover bandwagon to build competitive advantage. We discussed two different modeling approaches that provide complementary perspectives and insights to help management deal with issues of flexibility versus commitment: real options and dynamic game theory. While each approach separately might turn a blind eye to flexibility or commitment, an integrative perspective through "options games" might provide the right balance and serve as a tool kit for adaptive competitive strategy. Both perspectives ultimately aim to derive better insights into industry dynamics under industry conditions characterized by both market and strategic uncertainty.

Option games pave the way for a consistent approach in addressing managerial decision-making, elevating the art of strategy to scientific analysis. Option games integrates in a common, consistent framework recent advances made in

these diverse set of disciplines. This emerging field that represents a promising strategic management tool that can help guide managerial decisions through the complexity of the modern competitive marketplace.

Oscillator Synchronization

Bruce A. Francis
Department of Electrical and Computer Engineering, University of Toronto, Toronto, ON, Canada

Abstract

The nonlinear Kuramoto equations for n coupled oscillators are derived and studied. The oscillators are defined to be synchronized when they oscillate at the same frequency and their phases are all equal. A control-theoretic viewpoint reveals that synchronized states of Kuramoto oscillators are locally asymptotically stable if every oscillator is coupled to all others. The problem of synchronization in Kuramoto oscillators is closely related to rendezvous, consensus, and flocking problems in distributed control. These problems, with their elegant solution by graph theory, are discussed briefly.

Keywords

Graph theory; Kuramoto model; Laplacian; Oscillator; Synchronization

Introduction

An oscillator is an electronic circuit or other kind of dynamical system that produces a periodic signal. If several oscillators are coupled together in some fashion and the periodic signals that they each produce are of the same frequency and are in phase, the oscillators are said to be synchronized. The book *Sync: The Emerging Science of Spontaneous Order*, by Strogatz, introduces a wide variety of phenomena where oscillators synchronize. Some examples from biology: networks of pacemaker cells in the heart, circadian pacemaker cells in the suprachiasmatic nucleus of the brain,
Oscillator Synchronization, Fig. 1 Two metronomes on a board that is on two pop cans. After the metronomes are let go at the same frequency but at different times, they soon become synchronized and tick in unison.

metabolic synchrony in yeast cell suspensions, groups of synchronously flashing fireflies, and crickets that chirp in unison. Engineering examples include clock synchronization in distributed communication networks and electric power networks with synchronous generators.

A very simple example of oscillator synchronization was discovered by Christiaan Huygens, the prominent Dutch scientist and mathematician who lived in the 1600s. One of his contributions was the invention of the pendulum clock, where a pendulum swings back and forth with a constant frequency. Huygens observed that two pendulum clocks in his house synchronized after some time. The explanation for this phenomenon is that the pendula were coupled mechanically through the wooden frame of the house. The same principle can be observed by a fun, simple experiment. As in Fig. 1, put two pop cans on a table, on their sides and parallel to each other. Place a board on top of them, and place two (or more) metronomes on the board. Set the metronomes to tick at the same frequency. Start them off ticking but not in unison. Within a few minutes they will be ticking in unison.

In this essay we derive what are known as the Kuramoto equations, a mathematical model of n oscillators, and then we study when they will synchronize.

The Kuramoto Model

In 1975 the Japanese researcher Yoshiki Kuramoto gave one of the first serious mathematical studies of coupled oscillators. To derive Kuramoto's equations, we begin with a simple hypothetical setup. Imagine n runners going around a circular track. Suppose they're all going at roughly the same speed, but each adjusts his/her speed based on the speeds of his/her nearest neighbors. If some runner passes another, that one tends to speed up to close the gap. The synchronization question is do the runners eventually end up running together in a tight pack?

Idealize the runners to be merely points, numbered $k = 1, \ldots, n$. They move on the unit circle in the complex plane. A point on the unit circle can be written as $e^{j\theta}$, where j denotes the unit imaginary number and θ denotes the angle measured counterclockwise from the positive real axis. The position of point k at time t is $z_k(t) = e^{j(\omega t + \theta_k(t))}$, where ω is the nominal rotational speed in rad/s, and $\theta_k(t)$ is the difference between the actual angle at time t and the nominal angle ωt. Notice that ω is a constant positive real number and it is the same for all n points. As in circuit theory, it simplifies the mathematics to refer all the positions to the sinusoid $e^{j\omega t}$, and therefore we define the **local position** of point k to be $p_k(t) = z_k(t)/e^{j\omega t}$, i.e., $p_k(t) = e^{j\theta_k(t)}$. Differentiate the local position with respect to time and let "dot" denote d/dt: $\dot{p}_k = e^{j\theta_k} j \dot{\theta}_k$. Define the local rotational velocity $v_k = \dot{\theta}_k$ and substitute into the preceding equation:

$$\dot{p}_k = v_k j p_k. \tag{1}$$

The local velocity v_k could be positive or negative. Notice that if we view p_k as a vector from the origin and view multiplication by j as rotation by $\pi/2$, then $j p_k$ can be viewed as tangent to the circle at the point p_k – see the picture on the left in Fig. 2.

Now we propose a feedback law for v_k in Eq. (1); see the picture on the right in Fig. 2. Take v_k proportional to the projection of p_i onto the tangent at p_k, that is, $v_k = \langle p_i, j p_k \rangle$. Here the inner product between two complex numbers v, w is $\langle v, w \rangle = \text{Re } \bar{v} w$. (You may check that this is equivalent to the usual dot product of vectors in $\mathbb{R}^2$.) Thus from (1) the model to get k to close the gap is $\dot{p}_k = \langle p_i, j p_k \rangle j p_k$.
Oscillator Synchronization, Fig. 2 *Left*: The vectors p_k and jp_k. *Right*: The local velocity v_k

More generally, suppose that point k pays attention to not just point i but a fixed set of points called its **neighbors**. Let $\mathcal{N}_k$ denote the index set of neighbors of point k and for simplicity assume $\mathcal{N}_k$ does not depend on time. We consider the control law $v_k = \sum_{i \in \mathcal{N}_k} \langle p_i, jp_k \rangle$ and thereby arrive at the model of the evolution of the positions p_k:

$$\dot{p}_k = \sum_{i \in \mathcal{N}_k} \langle p_i, jp_k \rangle jp_k.$$

However, the Kuramoto model gives the evolution of the angles θ_k rather than the points p_k. To find the equation for θ_k, we observe that

$$\langle p_i, jp_k \rangle = \text{Re}\,(\bar{p}_i \, jp_k)$$
$$= \text{Re}\,(e^{-j\theta_i} j e^{j\theta_k})$$
$$= \sin(\theta_i - \theta_k).$$

In this way, the controlled points move according to

$$\dot{p}_k = \sum_{i \in \mathcal{N}_k} \sin(\theta_i - \theta_k) jp_k.$$

Substitute in $p_k = e^{j\theta_k}$ and then cancel jp_k:

$$\dot{\theta}_k = \sum_{i \in \mathcal{N}_k} \sin(\theta_i - \theta_k), \quad k = 1, \ldots, n. \quad (2)$$

This is the **Kuramoto model of coupled oscillators** in terms of the phases of the oscillators. There are n coupled nonlinear ordinary differential equations.

Equation (2) has the vector form $\dot{\theta} = g(\theta)$. There are some variations in the literature about

the state space associated with this equation. It is important to get the state space right because otherwise the concepts of stability and synchronization become shaky. The phase angles θ_k are real numbers with units of radians, so at first glance the state space is $\mathbb{R}^n$. But the angles are defined modulo 2π and so their values are restricted to lie in the interval $[0, 2\pi)$. In this way the state space becomes $[0, 2\pi)^n$. For example, if $n = 2$ the state space is the square $[0, 2\pi) \times [0, 2\pi)$ viewed as a subset of the plane $\mathbb{R}^2$. The mapping $\phi \mapsto e^{j\phi}$ is a one-to-one correspondence from the interval $[0, 2\pi)$ to the unit circle in the complex plane $\mathbb{C}$. This unit circle is usually denoted $\mathbb{S}^1$, the superscript signifying the circle's dimension as a manifold. By this correspondence the state space of (2) is the n-fold product $\mathbb{S}^1 \times \cdots \times \mathbb{S}^1$, and this is sometimes called the n-torus, denoted $\mathbb{T}^n$.

To recap, in what follows, the state space is $[0, 2\pi)^n$. This is an n-dimensional manifold rather than a vector space.

Synchronization

Control-theoretic methods, for example, that of Sepulchre et al. (2007), have been insightful. We address now the question of whether or not the oscillators in (2) synchronize, that is, the phases asymptotically converge to a common value. In the state space, $[0, 2\pi)^n$, the set of synchronized states is the set of vectors θ of the form $c\mathbf{1}$, where $c \in [0, 2\pi)$ and $\mathbf{1}$ is the vector of 1's. The simplest case is when every point is a neighbor of every other point, i.e., $\mathcal{N}_k$ contains every integer in the set $1, \ldots, n$ except k. Then (2) becomes

$$\dot{\theta}_k = \sum_{i=1}^{n} \sin(\theta_i - \theta_k), \quad k = 1, \ldots, n. \quad (3)$$

Let us show that if the initial phases $\theta_k(0)$ are all close enough together, then $\theta(t)$ converges asymptotically to a synchronized state. This will show that the synchronized states are locally asymptotically stable in a certain sense.

As stated before, Eq. (3) has the form $\dot{\theta} = g(\theta)$. The function $g(\theta)$ is the gradient of a

positive definite function. Indeed, let $re^{j\psi}$ denote the average of the points $e^{j\theta_1}, \ldots, e^{j\theta_n}$. Of course, r and ψ are functions of θ, and so we have

$$r(\theta)e^{j\psi(\theta)} = \frac{1}{n}\left(e^{j\theta_1} + \cdots + e^{j\theta_n}\right)$$

and therefore

$$r(\theta) = \frac{1}{n}\left|e^{j\theta_1} + \cdots + e^{j\theta_n}\right|.$$

The average of n points on the unit circle lives inside the unit disc, and therefore $r(\theta)$ is a real number between 0 and 1. It equals 1 if and only if the n points are equal, that is, the n phases are equal, and this is the state where the phases are synchronized.

Define the function

$$\begin{aligned}
V(\theta) &= \frac{n^2}{2}r(\theta)^2 \\
&= \frac{1}{2}\left|e^{j\theta_1} + \cdots + e^{j\theta_n}\right|^2 \\
&= \frac{1}{2}\left(e^{j\theta_1} + \cdots + e^{j\theta_n}\right)\left(e^{-j\theta_1} + \cdots + e^{-j\theta_n}\right).
\end{aligned}$$

Thus

$$\frac{\partial V(\theta)}{\partial \theta_k} = \sin(\theta_1 - \theta_k) + \cdots + \sin(\theta_n - \theta_k)$$

and therefore (3) can be written as $\dot{\theta} = \partial V(\theta)/\partial \theta$. This is a gradient equation. If $\theta(0)$ is chosen so that all the phases are close enough together, then $r(\theta(0))$ will be close to 1, and therefore θ will move in a direction to increase $V(\theta)$, that is, increase $r(\theta)$, until in the limit $r(\theta) = 1$ and the phases are synchronized.

There are results, e.g., Sepulchre et al. (2008), when the coupling is not all-to-all. Also, the term "synchronization" is used more generally than just for oscillators Wieland et al. (2011).

Rendezvous, Consensus, Flocking, and Infinitely Many Oscillators

Synchronization of coupled oscillators is closely related to other problems known as rendezvous,

consensus, or flocking problems. Phase synchronization is replaced by the requirement of mobile robots gathering at some location, by the requirement of temperature sensors in a sensor network converging to the same temperature estimate, or by the requirement that mobile robots should head in the same direction. The simplest form of these problems has the equations

$$\dot{\theta}_k = \sum_{i \in \mathcal{N}_k}(\theta_i - \theta_k), \quad k = 1, \ldots, n. \quad (4)$$

Notice that this can be obtained from the Kuramoto model (2) merely by replacing $\sin(\theta_i - \theta_k)$ by $\theta_i - \theta_k$ in (2), that is, by linearizing the latter at a synchronized state. We shall continue to call θ_k a phase of an oscillator. When do the phases evolving according to (4) synchronize? The answer to the question involves a lovely collaboration between graph theory and dynamics.

Introduce a directed graph that is in one-to-one correspondence with the neighbor structure. The graph is made up of n nodes, one for each oscillator. From each node there is an arrow to every neighbor of that node; that is, from node k is an arrow to every node in $\mathcal{N}_k$. Denote the adjacency matrix and the degree matrix of the graph by, respectively, A and D. That is, $a_{ij} = 1$ if j is a neighbor of i and d_{ii} equals the sum of the elements on row i of A. The **Laplacian** of the graph is defined to be $L = D - A$. Then (4) is equivalent to simply

$$\dot{\theta} = -L\theta, \quad (5)$$

where θ is still the vector with elements $\theta_1, \ldots, \theta_n$. Whether or not synchronization occurs depends on the connectivity of the graph. We stop here and refer the reader to the articles ▶ Averaging Algorithms and Consensus and ▶ Flocking in Networked Systems

Suppose there are an infinite but countable number of oscillators in the model (5). When will they synchronize? To answer this, we have to be more specific.

Let us allow an infinite number of oscillators numbered by the integers, positive, zero, and negative. Denote the phases by θ_k and let θ

denote the phase vector, whose kth component is θ_k. Assume each oscillator has only finitely many neighbors, let $\mathcal{N}_k$ denote the set of neighbors of oscillator k, and let L be the Laplacian of the associated graph. Finally, let $\theta(t)$ evolve according to the Eq. (5). This equation isn't automatically well posed in the sense that there may not be a solution defined for all $t > 0$. We have to impose a framework so that solutions do indeed exist. One natural space in which to place $\theta(0)$ is ℓ^2, the Hilbert space of square-summable sequences. If L is a bounded operator on ℓ^2, then so is e^{-Lt} for every $t > 0$, and hence the phase vector exists and belongs to ℓ^2 for every $t > 0$. Another natural space in which to place $\theta(0)$ is ℓ^∞, the Banach space of bounded sequences. Again, a phase vector exists for all $t > 0$ if L is a bounded operator on ℓ^∞.

The following example is from Feintuch and Francis (2012). Take the neighbor sets to be $\mathcal{N}_k = \{k - 1\}$. The graph is a chain: There is an arrow from node k to node $k - 1$, for every k, and the Laplacian is the infinite matrix with 1 on the diagonal, -1 on the first subdiagonal, and zero elsewhere. This Laplacian is a bounded operator on both ℓ^2 and ℓ^∞. Now the vector $c\mathbf{1}$, where $\mathbf{1}$ is the vector of all 1's, belongs to ℓ^∞ for every real number c, but it belongs to ℓ^2 only for $c = 0$. So the phases can potentially synchronize at any value in ℓ^∞, but only at 0 in ℓ^2. For the example under discussion, if the initial phase vector is in ℓ^2, then the phases synchronize at 0. By contrast, there exist initial phase vectors in ℓ^∞ such that synchronization does not occur. Even worse, $\lim_{t \to \infty} \theta(t)$ does not exist. The conclusion is that whether or not the oscillators will synchronize is a difficult question in general.

Summary and Future Directions

The Kuramoto model is a widely used paradigm for coupled oscillators. The model has the form $\dot{\theta} = f(E\theta)$, where θ is the vector of phases, the matrix E maps θ into the vector of possible differences $\theta_i - \theta_k$, and f is a function. The Kuramoto model considered in this essay is not the most general. A more general model allows different frequencies ω_k instead of just one, and also a coupling gain K, leading to the model

$$\dot{\theta}_k = \omega_k + \frac{K}{n} \sum_{i \in \mathcal{N}_k} \sin(\theta_i - \theta_k), \quad k = 1, \ldots, n.$$
(6)

An important problem associated with the Kuramoto model is to determine which synchronized states are stable. The linearized equation is interesting in its own right and relates to problems of rendezvous, consensus, and flocking.

Reference Dörfler and Bullo (2014) offers some questions for future study. In particular, it would be interesting to extend the Kuramoto model beyond the first-order oscillators of (2). Also, the case of general neighbor sets has much room for exploration.

Asymptotic stability is a robust property. For example, if the origin is asymptotically stable for the system $\dot{x} = Ax$, it remains so if A is perturbed by a sufficiently small amount. This is because the spectrum of a matrix is a continuous function of the matrix. The sketch in Fig. 1 vividly depicts the concept of synchronized oscillators. A topic for future study is that of robustness. Mathematically, if the two metronomes are identical, they will synchronize perfectly – this can be proved. Of course, physically two metronomes cannot be identical, and yet they will synchronize if they are close enough physically. A mathematical study of this phenomenon might be interesting.

Recommended Reading

The literature on the Kuramoto model is huge – there are now many hundreds of journal

papers continuing the study of oscillators using Kuramoto's model. There is space here only to highlight a few sources.

You can find a mathematical study of coupled metronomes in Pantaleone (2002). Also, Pantaleone's webpage Pantaleone describes some experimental observations. Kuramoto's original paper is Kuramoto (1975). Dörfler and Bullo have recently written a comprehensive survey (Dörfler and Bullo (2014)). Strogatz has written extensively on oscillator synchronization. His book *Sync* is fascinating and is highly recommended (Strogatz 2004). See also Strogatz (2000) and Strogatz and Stewart (1993). The papers Scardovi et al. (2007) and Dörfler and Bullo (2011) are recommended for more recent results, the latter treating the general model (6).

Getting phases in oscillators to synchronize is a special case of getting the states or outputs of coupled systems asymptotically to converge to a common value. There is a very large number of references on these subjects, a seminal one being Jadbabaie et al. (2003); others are Lin et al. (2007) and Moreau (2005). Regarding infinitely many oscillators, the physics literature treats only a continuum of oscillators, whereas countably many oscillators are the subject of Feintuch and Francis (2012).

Abstract

This entry discusses some of the salient features of the output regulation problem for hybrid systems, especially in connection with the steady-state characterization. In order to better highlight such peculiarities, the discussion is mostly focused on the simplest class of linear time-invariant systems exhibiting such behaviors. In comparison with the usual regulation theory, the role played by the zero dynamics and by the presence of more inputs than outputs is particularly striking.

Keywords

Disturbance rejection; Hybrid systems; Internal model principle; Output regulation; Tracking; Zero dynamics

Introduction

Output regulation is one of the most classical problems in control theory, and its celebrated solution in the linear time-invariant case (Davison 1976; Francis and Wonham 1976) is characterized by remarkable elegance and ideas (like the internal model principle). While the extension to nonlinear systems is still an active field of investigation, the study of output regulation for hybrid systems is also being actively pursued, and several surprising results have already appeared for the linear case, suggesting that a richer structure arises in hybrid output regulation problems due to the interplay between flow and jump dynamics.

The problem can be stated as follows. A known *exosystem* $\mathcal{E}$ with initial state belonging to a suitably defined set $\mathcal{W}_0$ produces a signal w possibly affecting both the *plant* $\mathcal{P}$ and the *compensator* $\mathcal{C}$; the compensator has to guarantee that for any initial state of $\mathcal{E}$ in a set $\mathcal{W}_0$:

- All closed-loop responses are bounded.
- The output e of $\mathcal{P}$ asymptotically converges to zero.

In order to avoid trivialities, the *exosystem* $\mathcal{E}$ is assumed to be such that its state evolution from nonzero initial states in $\mathcal{W}_0$ is bounded and not asymptotically converging to zero, both in forward and in backward time.

Two typical embodiments of the output regulation problem are the *disturbance rejection* and the *reference tracking* problems. In *disturbance rejection*, w acts as a disturbance on $\mathcal{P}$ and cannot be measured by $\mathcal{C}$, and the output e from which the effect of w has to be canceled is the actual plant output. In *reference tracking*, w contains the references to be tracked by an output y_r of $\mathcal{P}$, so that w can be assumed to be known by $\mathcal{C}$; by defining the regulated output e as $e = y_r - r$, the reference tracking problem is cast as an output regulation problem.

The solution of an output regulation problem entails the solution of two subproblems: the definition of a set of *zero output steady-state solutions* and the *asymptotic stabilization* of such solutions (or at least making them *attractive*; in many cases of interest, the achievement of this last objective actually yields asymptotic stabilization). As a matter of fact, the stabilization subproblem is already widely studied and described per se; for this reason, after some short remarks in section "Stabilization Obstructions in Hybrid Regulation", the remainder of this presentation will focus only on steady-state-related issues, for the simplest class of systems which exhibit the most peculiar and interesting phenomena of hybrid steady-state behavior (see in particular section "Key Features in Hybrid vs Classical Output Regulation"). For concreteness, only hybrid systems $\mathcal{E}, \mathcal{P}$ characterized by linear time-invariant (flow and jump) dynamics will be considered; following Goebel et al. (2012, Chap. 2), a two-dimensional parameterization of hybrid time $(t, k) \in \mathbb{R} \times \mathbb{N}$ will be used, with t measuring the flow of (usual) time and k counting the number of jumps experienced by the solution (see Fig. 1 for a specific example). So, the exosystem $\mathcal{E}$ will be described at time (t, k) by

$$\dot{w} = Sw, \qquad (w, t, k) \in \mathcal{C}_{\mathcal{E}}, \qquad (1a)$$

$$w^+ = Jw, \qquad (w, t, k) \in \mathcal{D}_{\mathcal{E}}, \qquad (1b)$$
Output Regulation Problems in Hybrid Systems, Fig. 1 Hybrid time domain $\mathcal{T}$ for a "sampled data" hybrid system. *Dots* indicate $(t, k) \in \mathcal{T}$ when jumps occur (see section "Hybrid Steady-State Generation" for the t_k notation)

and the plant $\mathcal{P}$ will be described at time (t, k) by

$$\dot{x} = Ax + Bu + Pw, \quad (x, u, t, k) \in \mathcal{C}_{\mathcal{P}}, \tag{2a}$$

$$x^+ = Ex + Rw, \qquad (x, u, t, k) \in \mathcal{D}_{\mathcal{P}}, \tag{2b}$$

$$e = Cx + Qw, \tag{2c}$$

with $x(t, k) \in \mathbb{R}^n$, $u(t, k) \in \mathbb{R}^m$, $e(t, k) \in \mathbb{R}^p$, $w(t, k) \in \mathbb{R}^q$, and suitably defined flow sets $\mathcal{C}_{\mathcal{E}}$, $\mathcal{C}_{\mathcal{P}}$ and jump sets $\mathcal{D}_{\mathcal{E}}$, $\mathcal{D}_{\mathcal{P}}$.

Stabilization Obstructions in Hybrid Regulation

The achievement of asymptotic stabilization of the desired (zero output) steady-state responses for the considered class of linear hybrid systems crucially depends on whether the plant $\mathcal{P}$ and the exosystem $\mathcal{E}$ have synchronous jump times or not.

Asynchronous Jumps

Typically, jumps in $\mathcal{P}$ and $\mathcal{E}$ will be asynchronous, and this will cause the undesirable phenomenon that genuinely close trajectories will look "distant" around each jump when the distance is measured according to the usual Euclidean norm. The simplest illustration of such phenomenon consists in considering two trajectories of the same system starting from ε-close initial conditions. Consider the system

$$\dot{v} = 1, \quad v \in [0, 1], \qquad v^+ = 0, \quad v \notin (0, 1),$$

with the initial states $v_0 = 0$ and $v_1 = \varepsilon$, $0 < \varepsilon < 1$. The two ensuing solutions at time (t, k) are immediately computed as

$$v(t, k; v_0) = t - k, \qquad t \in [k, k + 1],$$

$$v(t, k; v_1) = \begin{cases} t - k + \varepsilon, & t \in [k, k + 1 - \varepsilon], \\ t - k + \varepsilon - 1, & t \in [k + 1 - \varepsilon, k + 1], \end{cases}$$

Hence, the (Euclidean) distance between the two solutions at time (t, k) is given by

$$d(t, k) = \begin{cases} \varepsilon, & t \in [k, k + 1 - \varepsilon], \\ (1 - \varepsilon), & t \in [k + 1 - \varepsilon, k + 1]; \end{cases}$$

in other words, choosing $\varepsilon > 0$ as small as desired, arbitrarily close initial conditions generate trajectories which are apart by a finite amount (as close as desired to 1) during the arbitrarily small time intervals where $t \in [k + 1 - \varepsilon, k + 1]$. Since stability deals with trajectories remaining close forever and attractivity deals with trajectories getting closer and closer, examples such as the one above pose serious issues when defining (let alone establish) stability and attractivity in the hybrid case. Similar problems arise not only in output regulation problems but also in other areas like state tracking, observers, and general interconnections of hybrid systems.

However, intuition suggests (and mathematics confirms, by using a suitable notion of "distance") that such trajectories are close indeed. Several approaches have been proposed in order to overcome such difficulty. Considering as an example a bouncing ball tracking another bouncing ball, the problematic time intervals are those between the bounce of the first ball hitting the ground and the bounce of the other ball; in such a case, the modified distances are defined by either

- Allowing to exclude sufficiently short "problematic" intervals (possibly requiring that their length asymptotically tends to zero); see, e.g., Galeani et al. (2008, 2012)
- Considering alternative "mirrored" trajectories computed as if the last jump did not happen; see, e.g., Forni et al. (2013a,b)
- Using a "stretched" distance function δ such that when point a is in the jump set and its image via the jump map is $g(a)$, then $\delta(a, b) = \delta(g(a), b)$; see, e.g., Biemond et al. (2013).

While the first approach has been proposed first, the other two (which are strongly related) have the advantage of providing (under mild additional hypotheses) global control Lyapunov functions.

Finally, it is worth noting that the most adequate tools to address similar issues for general hybrid systems are the "graphical distance" among hybrid arcs and related concepts (see Goebel et al. 2012, Chap. 5).

Synchronous Jumps

When synchronous jumps are considered, the above issue disappears, and asymptotic stabilization becomes a much simpler matter. Although synchronous jumps look more like an exception than a rule in hybrid systems, they are very reasonable for specific classes of problems.

In order to have synchronous jumps, some authors have considered the use of "jump inputs" which *impose a jump at a certain time*, which can be physically reasonable in some systems, e.g., two tanks separated by a movable wall, assuming that when the wall is removed the fluid reaches the equilibrium configuration almost instantaneously.

Another relevant class consists of "sampled data" systems, whose jumps are essentially due to digital components which operate at a fixed sampling rate, which will be considered in the rest of this entry. In such a case, letting τ_M be the sampling period, the time domain of the hybrid system is fixed as (see Fig. 1)

$$\mathcal{T} := \{(t,k) : t \in [k\tau_M, (k+1)\tau_M], k \in \mathbb{Z}\}, \tag{3}$$

all jumps happen exactly for (t,k) with $t = (k+1)\tau_M$, and then (1) can be simplified as

$$\dot{w} = Sw, \tag{4a}$$
$$w^+ = Jw, \tag{4b}$$

and (2) can be simplified as

$$\dot{x} = Ax + Bu + Pw, \tag{5a}$$
$$x^+ = Ex + Rw, \tag{5b}$$
$$e = Cx + Qw, \tag{5c}$$

since flow and jump times are clear from the context.

For the latter class of systems, by using linear time-invariant hybrid control laws and observers

(and an easily provable separation principle), it is easily shown that:

- Under a hybrid stabilizability hypothesis, state feedback stabilization of (5) is easily achieved.
- Output feedback stabilization of (5) from e is also trivial under an additional hybrid detectability hypothesis.
- Under hybrid detectability of the cascade of (4) and (5), w can be asymptotically estimated from e.

Due to the above facts, it can be assumed without loss of generality that (5) is asymptotically stable (equivalently, that all eigenvalues of $Ee^{A\tau_M}$ have modulus strictly less than one). Asymptotic stability then yields *incremental stability*, since letting $\hat{x}$ and $\check{x}$ denote two motions under the same inputs u, w and only differing in their initial states, it is immediate to see that their difference $\tilde{x} := \hat{x} - \check{x}$ evolves as

$$\dot{\tilde{x}} = \dot{\hat{x}} - \dot{\check{x}} = A\hat{x} + Bu + Pw$$
$$- (A\check{x} + Bu + Pw),$$
$$\tilde{x}^+ = \hat{x}^+ - \check{x}^+ = E\hat{x} + Rw - (E\check{x} + Rw),$$

that is, $\dot{\tilde{x}} = A\tilde{x}$, $\tilde{x}^+ = E\tilde{x}$, and so it is just a free motion of the plant, asymptotically converging to zero. Incremental stability implies that *regulation is achieved as soon as it is shown that for any exogenous input w it is possible to find an input u and an initial state of* (5) *such that e is identically zero*, since then any other motion arising from a different initial state will asymptotically converge to the motion with identically zero e. Moreover, it is easy to see that asymptotic stability of the origin actually implies uniform, global, and exponential stability of any trajectory for such systems.

Hybrid Steady-State Generation

From this point on, the rest of the presentation will be focused only on the case where the problem data are of the form (3) to (5), since this allows to provide an uncluttered view on some

peculiar features of hybrid steady-state motions, without the burden of having to take care of delicate stability issues arising in more general contexts.

Based on the preceding discussion, there is no loss of generality at this point in assuming that:

- *Plant* (5) *is asymptotically stable*, which is equivalent to all eigenvalues of $Ee^{A\tau_M}$ having a magnitude strictly less than one.
- *Exosystem* (4) *is Poisson stable*, which is equivalent to all eigenvalues of $Je^{S\tau_M}$ having a magnitude equal to one.

It is also customary to distinguish between *full information* and *error feedback* regulation, where in the first case controller $\mathcal{C}$ has access to the complete state (w, x) of the cascade of $\mathcal{E}$ and $\mathcal{P}$, whereas in the second case $\mathcal{C}$ can only measure the output e of $\mathcal{P}$.

Having assumed asymptotic stability of plant $\mathcal{P}$, the only role of compensator $\mathcal{C}$ consists in generating the correct steady-state input, since then, by incremental stability of $\mathcal{P}$, asymptotic regulation is ensured from any initial state. Recalling the expression of $\mathcal{T}$ in (3), for the following developments it is useful to define the jump times t_k and the elapsed time of flow since last jump σ as

$$t_k := k\tau_M, \qquad \sigma(t, k) := t - k\tau_M;$$

the arguments of $\sigma(t, k)$ will usually be omitted since clear from the context. Note that σ satisfies $\dot{\sigma} = 1$, $\sigma^+ = 0$, and it is often explicitly introduced as an additional *timer* variable.

The Full Information Case

Consider the candidate steady-state motion and input:

$$\begin{bmatrix} x_{ss}(t, k) \\ u_{ss}(t, k) \end{bmatrix} = \begin{bmatrix} \Pi(\sigma) \\ \Gamma(\sigma) \end{bmatrix} w(t, k). \qquad (6)$$

Requiring that such expressions actually characterize a response of the considered plant, as well as the associated output is zero, amounts to ask that:

- During flows, $\dot{x}_{ss}(t, k)$ has to satisfy the two equations:

$$\dot{x}_{ss}(t, k) = \dot{\Pi}(\sigma)w(t, k) + \Pi(\sigma)\dot{w}(t, k),$$

$$\dot{x}_{ss}(t, k) = Ax_{ss}(t, k) + Bu_{ss}(t, k)$$
$$+ Pw(t, k).$$

- At jumps, $x_{ss}^+(t, k)$ has to satisfy the two equations:

$$x_{ss}^+(t_{k+1}, k) = \Pi(0)w^+(t_{k+1}, k),$$

$$x_{ss}^+(t_{k+1}, k) = Ex_{ss}(t_{k+1}, k) + Rw(t_{k+1}, k).$$

- For the output e_{ss} to be identically zero:

$$0 = Cx_{ss}(t, k) + Qw(t, k).$$

Substituting (6) in the above conditions and considering that such relations should hold for all values of w, the following *hybrid regulator equations* are obtained:

$$\dot{\Pi}(\sigma) + \Pi(\sigma)S = A\Pi(\sigma) + B\Gamma(\sigma) + P, \qquad (7a)$$

$$\Pi(0)J = E\Pi(\tau_M) + R, \qquad (7b)$$

$$0 = C\Pi(\sigma) + Q. \qquad (7c)$$

Equations (7) can be shown to be both necessary and sufficient for (6) to solve the output regulation problem under the considered assumptions. Once a solution of (7) is available, the full information regulator simply reduces to the time-varying static feedforward controller

$$u(t, k) = \Gamma(\sigma)w(t, k) \qquad (8)$$

which just provides as input the steady-state input u_{ss} characterized as in (6); in fact, since (5) is incrementally stable (as follows from its asymptotic stability, which was assumed without loss of generality), its output response under the control law (8) must converge to the output response associated to (6).

For later use, note that in the non-hybrid case where $\mathcal{P}$ and $\mathcal{E}$ only flow

$$\dot{w} = Sw, \qquad (9a)$$

$$\dot{x} = Ax + Bu + Pw, \qquad (9b)$$

$$e = Cx + Qw, \qquad (9c)$$

the candidate steady state (6) is replaced by

$$\begin{bmatrix} x_{ss}(t) \\ u_{ss}(t) \end{bmatrix} = \begin{bmatrix} \Pi \\ \Gamma \end{bmatrix} w(t), \qquad (10)$$

and (7) reduces to the celebrated *regulator equations* (or *Francis equations*)

$$\Pi S = A\Pi + B\Gamma + P, \qquad (11a)$$

$$0 = C\Pi + Q, \qquad (11b)$$

and, as above, assuming without loss of generality that the plant is asymptotically stable, the full information regulator reduces to the time-invariant static feedforward controller:

$$u(t, k) = \Gamma w(t, k) \qquad (12)$$

The Error Feedback Case

When the exosystem state is not measured, a dynamic compensator of the form

$$\dot{\xi} = F\xi + Ge, \qquad (13a)$$

$$\xi^+ = L\xi, \qquad (13b)$$

$$u = H\xi, \qquad (13c)$$

which is also supposed to flow and jump according to the a priori fixed time domain $\mathcal{T}$ considered for the plant, is introduced, and the corresponding candidate steady-state motion including ξ is

$$\begin{bmatrix} x_{ss}(t, k) \\ \xi_{ss}(t, k) \\ u_{ss}(t, k) \end{bmatrix} = \begin{bmatrix} \Pi(\sigma) \\ \Sigma(\sigma) \\ \Gamma(\sigma) \end{bmatrix} w(t, k). \qquad (14)$$

By following similar steps as above, requiring invariance of such a manifold in the space of (x, ξ, u, w), as well as zero output on it, leads to the conclusion that in addition to (7), the following relations must be satisfied as well:

$$\dot{\Sigma}(\sigma) + \Sigma(\sigma)S = F\Sigma(\sigma), \qquad (15a)$$

$$\Sigma(0)J = L\Sigma(\tau_M). \qquad (15b)$$

$$\Gamma(\sigma) = H\Sigma(\sigma), \qquad (15c)$$

Equations (7) and (15) can be shown to be both necessary and sufficient for (13) to solve the output regulation problem under the considered assumptions and generalize the corresponding conditions for the non-hybrid case where $\mathcal{P}$ and $\mathcal{E}$ only flow (see (9)) and (13) and (14) are replaced by

$$\dot{\xi} = F\xi + Ge, \qquad (16a)$$

$$u = H\xi, \qquad (16b)$$

$$\begin{bmatrix} x_{ss}(t) \\ \xi_{ss}(t) \\ u_{ss}(t) \end{bmatrix} = \begin{bmatrix} \Pi \\ \Sigma \\ \Gamma \end{bmatrix} w(t), \qquad (16c)$$

and (15) reduces to

$$\Sigma S = F\Sigma, \qquad (17a)$$

$$\Gamma = H\Sigma. \qquad (17b)$$

Relations (17) are an expression of the *internal model principle*, stating that in order to achieve error feedback regulation, the compensator $\mathcal{C}$ must include a suitable "copy" of the exosystem, namely, (17a) imposes a constraint on the ξ dynamics of $\mathcal{C}$ which, coupled with (17b), ensures that the signal $u_{ss} = \Gamma w$ used in the full information case can be equivalently produced (without measuring w!) as $u_{ss} = H\Sigma\xi$. A similar interpretation can be given to (15), which must be required in addition to (7) in order for (13) to solve the hybrid error feedback output regulation problem.

Key Features in Hybrid vs Classical Output Regulation

While the previous section mainly aimed at showing how the classical theory generalizes in the hybrid case (at least for a special class of hybrid systems), the aim of this section is to point out some of the striking differences between the two

cases. Before proceeding further, and in order to keep focus on the characterization of the steady-state response, it is worth mentioning here that although time-varying systems will be considered, no issue regarding nonuniform stability (like in general nonautonomous systems) arises since the timer σ just ranges in the compact set $[0, \tau_M]$ due to the assumed periodic structure of $\mathcal{T}$ (see also the end of section "Synchronous Jumps").

Comparing the classical and the hybrid output regulator and considering that $\mathcal{P}$ and $\mathcal{E}$ are time invariant, it seems somewhat strange that in the output feedback case the linear time-invariant regulator (16a) and (16b) generalizes to a hybrid linear time-invariant regulator (13), whereas in the full information case the linear time-invariant regulator (12) generalizes to a hybrid linear *time-varying* regulator (8).

One argument in favor of the *time-varying* regulator (8) is based on the following consideration. It is well known that (11) has a unique solution in the case of a square plant ($m = p$) under the *nonresonance condition* between the zeros of $\mathcal{P}$ and the eigenvalues of $\mathcal{E}$, requiring that

$$\text{rank} \begin{bmatrix} A - sI & B \\ C & 0 \end{bmatrix} = n + p, \quad \forall s \in \Lambda(S),$$

where $\Lambda(S)$ denotes the spectrum of S. In such a case, (11) amounts to a system of $nq + pq$ linear equations in $nq + mq$ unknowns (the elements of Π, Γ), which might be expected to be satisfied since $m \geq p$. If one were trying to use the unique constant solution (Π, Γ) of (11) as a solution of (7), clearly (7a) and (7c) would be satisfied, but then (7b) would impose other nq equations on Π which would unlikely be satisfied. For this reason, apparently the additional degree of freedom offered by choosing time dependent Π and Γ might be of help. In fact, it can be shown that if $m = p$ and under a hybrid nonresonance condition (involving $Ee^{A\tau_M}$ and $Je^{S\tau_M}$) between $\mathcal{P}$ and $\mathcal{E}$, (7a) and (7b) have a unique solution for any choice of $\Gamma(\sigma)$, so that the design boils down to satisfying (7c) by choosing $\Gamma(\sigma)$; but is this always possible? In order to answer this nontrivial question, a different path must be followed. While a complete formal analysis can

be performed, the following discussion will be mainly based on showing the simplest examples exhibiting the pathologies of interest.

Consider the system with $\tau_M = 1$ (so that $t_k = k$, for all $k \in \mathbb{Z}$) and

$$\dot{w} = 0, \tag{18a}$$

$$w^+ = -w, \tag{18b}$$

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w, \tag{18c}$$

$$\begin{bmatrix} x_1^+ \\ x_2^+ \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 2e & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}, \tag{18d}$$

$$e = \begin{bmatrix} 0 & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} - w. \tag{18e}$$

The unique steady-state solution achieving output regulation can be simply computed. In fact, by (18a) and (18b),

$$w(t, k) = (-1)^k w(0, 0);$$

then, by (18e) it appears that $e_{ss} = 0$, $\forall (t, k) \in \mathcal{T}$ implies

$$x_{2,ss}(t, k) = w(t, k) = (-1)^k w(0, 0),$$

$$\forall (t, k) \in \mathcal{T},$$

which in turn implies that $\dot{x}_{2,ss} = 0$ for all $t \in (k, k+1)$, $k \in \mathbb{Z}$ and the unique steady-state input

$$u_{ss} = 2x_{2,ss} - w.$$

Since (18d) implies that $x_{1,ss}(t_{k+1}, k+1) = x_{2,ss}(t_{k+1}, k) = w(t_{k+1}, k)$ and (18c) implies that $x_{1,ss}(t, k) = -e^{-(t-k)}x_{1,ss}(t_k, k)$, for $t \in (t_k, t_{k+1})$, it follows that

$$x_{1,ss}(t, k) = -e^{-(t-t_k)}w(t_k, k), \quad t \in (t_k, t_{k+1}), \tag{19}$$

which finally is coherent with the jump equation for $x_{2,ss}$ in (18d) since

$$x_{2,ss}(t_{k+1}, k+1) = 2ex_{1,ss}(t_{k+1}, k) + x_{2,ss}(t_{k+1}, k)$$

$$= 2e(-e^{-1})w(t_k, k) + w(t_k, k) \tag{20a}$$

$$= -w(t_k, k) \tag{20b}$$

$$= (-1)^{k+1}w(0, 0). \tag{20c}$$

Before commenting the meaning of the above derived steady-state evolution, it is worth noting that (18) might actually derive from an original system with (18c) replaced by

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} -1 & 0 \\ 1 & -2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w, \tag{21}$$

under the preliminary state feedback

$$u = -x_1 + v. \tag{22}$$

Such a feedback renders the subspace $\{x : x_2 = 0\}$ unobservable (when the system only flows) and reveals that the dynamics of x_1 in (18c) is the *flow zero dynamics* of $\mathcal{P}$, that is, the zero dynamics of $\mathcal{P}$ when jumps are inhibited. Having set the stage, several interesting observations can be made now.

The flow zero dynamics samples the exogenous signal w at jumps and then evolves according to its own modes (see (19)). In fact, while in the classical case (10) the state and input at steady state can be expressed as a constant matrix times the current value of w, the real nature of the time dependence of Γ and Π in (6) is linked to this phenomenon of *sampling $w(t_k, k)$* and *propagating along the zero dynamics*. A suitable analysis shows that $\Pi(\sigma)$, $\Gamma(\sigma)$ contain products of matrices with rightmost factor $e^{-S\sigma}$ (which recovers $w(t_k, k) = e^{-S\sigma}w(t, k)$ from the current value $w(t, k)$ of w) and leftmost factor containing the fundamental matrix of the flow zero dynamics. It is worth mentioning that the "motion along the zeros" in the present context is strongly related to the same kind of motions used for perfect tracking in non-hybrid systems. The above insight about the nature of the dependence on σ in (6) also reveals why in the output feedback case (13) such dependence is not needed: the required modes of the flow zero dynamics in

that case are provided by copying them in the compensator dynamics!

An even stronger consequence of the analysis above is a **flow zero dynamics internal model principle**, which essentially states that any output feedback compensator solving the output regulation problem must be able to produce as free responses (during flow) a suitable subset of the natural modes of the flow zero dynamics (and a suitably modified version applies to the feedforward static compensator (8)). It is worth noting that while the classical internal model principle requires exact knowledge of the exosystem modes (which is kind of a mild requirement, especially when the exosystem models references, or constant offsets), the *flow zero dynamics internal model principle* requires the exact knowledge of the modes of the zero dynamics, which typically depends on not precisely known plant parameters; clearly, this fact poses serious questions in view of the achievement of robust regulation.

A final point, also raising serious issues about what can be robustly achieved (and how) in the setting of hybrid output regulation, is the fact that **generically, existence of solutions is not robust to arbitrarily small parameter variations.** In particular, looking again at the computations in (20), it should be clear that the involved functions are all fixed by previous reasonings, whereas satisfaction of (20) crucially depends on exact cancellations of certain coefficients. Any small variations of such coefficients in (18d) imply that the problem admits no steady state yielding zero output. This fact is in sharp contrast with classical regulation, where the nonresonance condition ensures existence of (different) solutions for small parameter variations. It has to be noted, though, that **under additional conditions, robust existence of solutions is guaranteed if the plant is fat**, that is, $m > p$. Using again the previous example, this is the case if an additional input is introduced

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} w,$$

since then even a constant (suitably chosen) value of u_1 can be used to ensure that when the time to

jump arrives, the value of x_1 is such to ensure a correct jump for x_2 (remember that since x_1 is unobservable during flows, its motion can be changed as wished if this helps with ensuring that the observable x_2 achieves zero output).

Summary and Future Directions

The investigation of the output regulation problem for hybrid systems is still at a very early stage. While the issues of stabilization of the manifold where regulation is achieved seem to be a relatively better understood topic (possibly drawing from a richer literature on stabilization of hybrid systems), the geometry and design of such manifold appear to involve several much more intricate issues, whose understanding will be crucial in order to achieve more complete solutions.

Already in the very simplified case of linear dynamics and synchronous jumps, the important role played by the whole flow zero dynamics for feasibility (existence of solutions in the nominal parameter values) and by the availability of more inputs than outputs for well posedness (existence of solutions for slightly perturbed parameter values) marks a strong difference with the linear non-hybrid case, where both properties are granted by satisfaction of the nonresonance condition, which only involves the spectrum of the zero dynamics, even for square plants.

While the expected final goal of this investigation should hopefully lead to the design of robust output regulators based on a suitable internal model principle, a deeper understanding of the structure of the steady-state motion achieving regulation, as well as of the effect of additional inputs in shaping it, seems to be an important preliminary step towards such goal.

Recommended Reading

Foundational contributions on classical output regulation are Francis and Wonham (1976), Davison (1976), and Wonham (1985); more recent monographs include Huang (2004), Trentelman et al. (2001), Pavlov et al. (2005), Saberi et al. (2000), and Byrnes et al. (1997). Goebel et al. (2012) provides a solid introduction to a powerful and elegant framework for hybrid systems, including a thorough discussion of stability issues related to those mentioned here. Regulation problems (mainly reference tracking) for classes of hybrid systems with asynchronous jumps are presented in Biemond et al. (2013), Forni et al. (2013a,b), Morarescu and Brogliato (2010), and Galeani et al. (2008, 2012); synchronous jumps (and the ensuing advantages) are considered e.g., Sanfelice et al. (2013). The class of linear systems with synchronous jumps considered in sections "Hybrid Steady State Generation" and "Key Features in Hybrid vs Classical Output Regulation" has been proposed in Marconi and Teel (2010, 2013) and studied in Cox et al. (2011, 2012); the issues related to flow zero dynamics, fat plants and robustness have been discussed in Carnevale et al. (2012a,b, 2013), partly developing remarks contained in Galeani et al. (2008, 2012).

Parallel Robots

Frank C. Park
Robotics Laboratory, Seoul National University,
Seoul, Korea

Abstract

Parallel robots are closed chains consisting of a
fixed and moving platform that are connected by
a set of serial chain legs. Parallel robots typically
possess both actuated and passive joints and may
even be redundantly actuated. Although more
structurally complex and possessing a smaller
workspace, parallel robots are usually designed
to exploit one or more of the natural advantages
they possess over their serial counterparts, e.g.,
higher stiffness, increased positioning accuracy,
and higher speeds and accelerations. In this chap-
ter we provide an overview of the kinematic
and dynamic modeling of parallel robots, a de-
scription of their singularity behavior, and basic
methods developed for their control.

Keywords

Closed kinematic chain; Closed loop mechanism;
Parallel manipulator

Introduction

A parallel robot refers to a kinematic chain in
which a fixed platform and moving platform
are connected to each other by several serial
chains, or legs. The legs, which typically have
the same kinematic structure, are connected to
the fixed and moving platforms at points that are
distributed in a geometrically symmetric fashion.
The Stewart-Gough platform (Fig. 1) is a well-
known example of a parallel robot: each of the
six legs is a *UPS* structure (i.e., consisting of
rigid links serially connected by a universal, pris-
matic, and spherical joint), with the prismatic
joint actuated. Other examples of parallel robots
include the $6 \times RUS$ platform of Fig. 2, the
haptic interface device of Fig. 3, and the eclipse
mechanism of Fig. 4.

Parallel robots can be regarded as a special
class of closed chain mechanisms (i.e., chains
that contain one or more closed loops) and are
purposely designed to exploit the specific ad-
vantages afforded by the closed chain structure,
e.g., for improved stiffness, greater positioning
accuracy, or higher speed. Parallel robots should
be distinguished from two or more cooperating
serial robots that may form closed loops during
execution of a task (e.g., a robotic hand grasping
an object). Some of the fastest velocities and
accelerations recorded by industrial robots have
been achieved by parallel robots, primarily by
Parallel Robots, Fig. 1 Stewart-Gough platform

placing the actuators on the fixed platform and thereby minimizing the mass of the moving parts.

Many of the model-based techniques developed for the control of traditional serial chain robots are also applicable to a large class of parallel robots. On the other hand, kinematic and dynamic models for parallel robots are inherently more complex. Parallel robots also possess features not found in serial robots, e.g., passive joints, the possibility of redundant actuation, and a diverse range of singularity behavior, that need to be considered when designing a control law. We therefore begin with a brief overview of the kinematic and dynamic modeling of parallel robots before discussing their control.

Modeling

Kinematics

Whereas the kinematic degrees of freedom, or mobility, of a serial chain robot can be obtained as the sum of the degrees of freedom of each of the joints, the situation is somewhat more complex for parallel robots and closed chains in general, since only a subset of the joints can be independently actuated. The mobility of a parallel robot corresponds to the total degrees of freedom of the joints that can be independently actuated. In some cases the number of actuated joint degrees

of freedom may exceed the kinematic degrees of freedom, in which case we say that the robot is redundantly actuated.

A parallel robot with a designated end-effector frame also has a notion of forward and inverse kinematics. While for serial chains the forward kinematics is a well-defined mapping and the inverse kinematics can typically have multiple solutions, for parallel robots the situation is less straightforward. For the Stewart-Gough platform of Fig. 1, in which the leg lengths can be adjusted by actuating the prismatic joints, the inverse kinematics is unique and straightforward to obtain, whereas the forward kinematics will have multiple solutions. For other types of parallel robots in which the legs themselves contain one or more closed loops, both the forward and inverse kinematics can have multiple solutions.

The notion of kinematic singularities for parallel robots is also much more involved than the case for serial robots. Whereas kinematic singularities for serial chain robots are characterized by configurations at which the forward kinematics Jacobian (i.e., the linear mapping relating joint velocities to end-effector frame velocities) becomes singular, for parallel robots and closed chains in general, there exist other notions of singularities not found in serial chains. For example, given a parallel robot with kinematic mobility m – if the parallel robot consists only of one degree-of-freedom joints, this implies that exactly m joints can be actuated – there may exist configurations in which these m joints cannot be independently actuated. Conversely, even if the m actuated joints are each fixed to some value, the parallel robot may fail to be a structure, i.e., some of the links may be able to move.

In the above scenario, choosing a different set of m actuated joints may remedy this situation, in which case such singularities are referred to as actuator singularities. Configurations at which singularity behavior occurs regardless of which joints are actuated are denoted configuration singularities. The final class of singularities are end-effector singularities, which correspond to the usual serial chain notion of kinematic singularity, in which the end-effector loses one or more degrees of freedom of available motion.

Parallel Robots, Fig. 3 A $3 \times PUU$ haptic interface
Parallel Robots, Fig. 4 The $3 \times PPRS$ eclipse parallel mechanism

Dynamics

In the case of a parallel robot whose actuated degrees of freedom coincides with its kinematic mobility m, it is possible to choose an independent set of generalized coordinates of dimension m, denoted $q \in \mathbb{R}^m$ and typically identified with the actuated joints, and to express the dynamics in the standard form

$$M(q)\ddot{q} + C(q, \dot{q})\dot{q} + G(q) = \tau, \quad (1)$$

where $\tau \in \mathbb{R}^m$ denotes the vector of input joint torques, $M(q)$ denotes the $n \times n$ mass matrix, the matrix-vector product $C(q, \dot{q})\dot{q}$ denotes the vector of Coriolis terms, and $G(q) \in \mathbb{R}^m$

denotes the vector of gravitational forces. The structure of the dynamic equations is identical to that for serial chain robots. Also like the case for serial chain robots, the Coriolis matrix term $C(q, \dot{q}) \in \mathbb{R}^{m \times m}$ is not unique, so that one should ensure that the correct $C(q, \dot{q})$ is used in, e.g., any control law whose stability depends on the matrix $\dot{M}(q) - 2C(q, \dot{q})$ being skew-symmetric.

It is also important to keep in mind that the q must satisfy the kinematic constraint equations imposed by the loop closure constraints. That is, if $\theta \in \mathbb{R}^n$ denotes the vector of all joints (both actuated and passive), then $q \in \mathbb{R}^m$, $m \leq n$, will be a subset of θ whose values can only be obtained by solution of the kinematic constraint equations; depending on the nature of the kinematic constraints, one may have to resort to iterative numerical methods.

If the parallel robot is redundantly actuated, then the dynamics are subject to a further set of constraints on the input torques. Letting q_e denote the set of independent generalized coordinates and q_a be the vector of all actuated joints, the vector of actuated joint torques τ_a must then further satisfy $S^T \tau_a = W^T \tau$, where τ denotes the vector of joint torques for an equivalent tree structure system that moves identically to the redundantly actuated parallel robot and W and S are defined, respectively, by

$$S = \frac{\partial \theta}{\partial q_e}, \quad W = \frac{\partial q_a}{\partial q_e}. \quad (2)$$

Compared to the dynamics for serial chain robots, the dynamics for parallel robots is, in general, considerably more complex and computationally involved. The recursive algorithms that are available for computing the inverse and forward dynamics of serial chain robots can also be used to develop similar recursive algorithms for parallel robot dynamics; however, the computations will be considerably more involved and require multiple iterations.

Motion Control

Exactly Actuated Parallel Robots

For parallel robots whose actuated degrees of freedom match the kinematic mobility (this excludes the set of all redundantly actuated parallel robots), most control laws developed for serial chain robots are also applicable. This is not altogether surprising in light of the similarity in the structure of the kinematic and dynamic equations between serial and parallel robots. Control

laws for serial robots are also covered in this handbook, and we refer the reader to ▶ Linear Matrix Inequality Techniques in Optimal Control for the essential details. Here we summarize the most basic control laws and point out any additional computational or other requirements that are needed when applying these laws to parallel robots. Note that other control laws and techniques developed for serial chain robots, e.g., robust, sliding mode, can also be applied with the same additional considerations and requirements outlined below:

1. **Computed torque control**: Computed torque control for parallel robots has the same control law structure as for serial robots, i.e.,

$$\tau = M(q)\left(-K_p e - K_v \dot{e}\right) + \tau_{ff}, \quad (3)$$

where e denotes the tracking error, K_p and K_v are the proportional and derivative feedback gain matrices, and τ_{ff} denotes the feedforward term required to cancel the nonlinear dynamics. Robust versions of computed torque control are also applicable to parallel robots under the same set of conditions, e.g., establishing appropriate bounds on the mass matrix eigenvalues and on the norm of the Coriolis matrix.

2. **Augmented PD control**: The augmented PD control law for serial robots is also applicable to parallel robots, i.e.,

$$\tau = -K_p e - K_v \dot{e} + M(q)\ddot{q}_d + C(q,\dot{q})\dot{q} + G(q), \quad (4)$$

where q_d is the reference trajectory to be tracked and K_p and K_v are the proportional and derivative feedback gains. Asymptotic stability is also established under the same conditions.

3. **Adaptive control**: Because the dynamic equations for parallel robots are also linear in the link mass and inertial parameters, i.e.,

$$M(q)\ddot{q} + C(q,\dot{q})\dot{q} + G(q) = \Phi(q,\dot{q},\ddot{q})p, \quad (5)$$

where p denotes the vector of link mass and inertial parameters, adaptive control laws developed for serial robots can also be used.

4. **Other control methods**: There exist numerous control methods developed for serial robots, e.g., task space or operational space control, sliding mode control, and various nonlinear control techniques; with few exceptions most of these algorithms can also be applied to exactly actuated parallel robots with minimal modification.

Redundantly Actuated Parallel Robots

As described earlier, parallel robots exhibit a much more diverse range of singularity behavior than their serial counterparts, many of which depend on the choice of actuated joints (actuator singularities). One way to eliminate actuator singularities is via redundant actuation, i.e., the total degrees of freedom of the actuated joints exceeds the kinematic mobility of the mechanism. Redundant actuation offers some protection in the event of failed actuators and, when combined with an appropriate control law, offers an effective means of reducing joint backlash, increasing speed and payload and stiffness, controlling compliance through the generation of internal forces, and even improving power efficiency (as an analogy, the human musculoskeletal system is redundantly actuated by antagonistic muscles). Of course, redundant actuation introduces a new set of control challenges, since the control inputs must be designed so as not to conflict with the kinematic constraints inherent in the parallel robot; loosely speaking, the actuated joints can no longer be independently controlled, since the consequences of unintended antagonistic actuation may be catastrophic.

The control of cooperating manipulators (see ▶ Optimal Control and Mechanics) has a long history in robotics, and many of the control techniques developed for such multi-arm systems can also be applied to redundantly actuated parallel robots. One can also apply the control strategies developed for exactly actuated parallel robots to the redundantly actuated case, but modifications

are necessary to account for the different structure of the dynamic equations.

Like all model-based control algorithms, the above control laws are subject to model uncertainties. Whereas in serial chains the effects of model uncertainty simply lead to errors in tracking, for redundantly actuated parallel robots, the consequences can lead to internal forces in addition to end-effector tracking errors. Perhaps the most significant effect of any modeling errors is that, unlike the serial chain case, the kinematic errors can potentially alter the shape of the configuration space (recall that the configuration space will in general be a curved space for closed chains) and also interfere with any PD feedback introduced into the control. The development of control laws that are robust to such modeling errors and disturbances remains an open and ongoing area of research in parallel robot control.

Force Control

Both hybrid force-position control and impedance control are well-known and widely applied concepts in serial robots and can be extended in a straightforward manner to exactly actuated parallel robots. Recall that the basic feature of hybrid force-position control is that the task space is decomposed into force- and position-controlled directions, whereas in impedance control, the goal is have the robot maintain a certain desired spatial stiffness in the task space. Controllers that combine aspects of force-position and impedance control have also been proposed and developed for both serial robots and exactly actuated parallel robots. Modeling errors will cause deviations in both the force- and position-controlled directions – leading to motions in force-controlled directions and forces in position-controlled directions – which can be addressed by, e.g., a switching control strategy.

The problem of force control for redundantly actuated parallel robots, which encompasses both force-position and impedance control, has also received some attention in the literature.

The main difference with the exactly actuated case is that internal forces can now be generated, which requires a more detailed and coordinate-invariant examination of stiffness. Control methods that combine elements of force-position and impedance control for redundantly actuated parallel robots have received only limited attention in the literature.

Particle Filters

Fredrik Gustafsson
Division of Automatic Control, Department of
Electrical Engineering, Linköping University,
Linköping, Sweden

Abstract

The particle filter computes a numeric approximation of the posterior distribution of the state trajectory in nonlinear filtering problems. This is done by generating random state trajectories and assigning a weight to them according to how well they predict the observations. The weights are instrumental in a resampling step, where trajectories are either kept or thrown away. This exposition will focus on explaining the main principles and the main theory in an intuitive way, illustrated with figures from a simple scalar example. A real-time application is used to graphically show how the particle filter solves a nontrivial nonlinear filtering problem.

Keywords

Estimation; Kalman filter; Nonlinear filtering; Sequential Monte Carlo

Introduction

The particle filter computes an arbitrarily good solution to nonlinear filtering problems. The goal in nonlinear filtering is to compute the posterior distribution of the state vector in a dynamic model, given measurements that are related to the state. Bayes rule provides a recursive but computationally intractable solution. Monte Carlo (MC) methods can essentially solve all Bayesian inference problems.

However, for nonlinear filtering, the complexity increases exponentially in time. The MC approach would be to generate a large number of state trajectories (called particles) and their corresponding sequences of predicted measurements and then weighs together the trajectories according to how well the predicted and actual measurement sequences match each other.

With increasing time, the fit is deemed to be poor, since the state space increases exponentially in time. This is usually referred to as the depletion (or degeneracy) problem. The approach in the particle filter is to simulate only one step at the time and then resample the trajectories if needed. For this reason, the particle filter is sometimes referred to as a sequential Monte Carlo method. The resampling step keeps the trajectories that give a good fit, while the bad ones are discarded. The novel idea in the particle filter when it was first published in 1993 was the introduction of this resampling step.

Depletion is still a problem, despite the resampling step. Mitigating depletion has ever since the beginning been the most pressing issue in applied particle filtering. This tutorial will present the basic particle filter algorithm and discuss ways to avoid depletion problems both in general terms and in a simple example.

The particle filter computes an approximation to the Bayes optimal filter, conditioned on a sequence of observations and a nonlinear non-Gaussian system. It is important to note that the PF approximates the posterior distribution of the state trajectory, from which the mean and covariance are easily extracted. In contrast, the extended Kalman filter (EKF) computes the mean and covariance for an approximate dynamical system (linearized with Gaussian noise). The unscented Kalman filter (UKF) likewise also approximates the mean and covariance. Both EKF and UKF can only approximate unimodal (one peak) posterior distributions. There are filter bank approximations, like the interacting multiple model (IMM) algorithm, that can keep track of a given number of modes in the posterior.

P

However, the PF does this in a more natural way.

The Basic Particle Filter

Nonlinear filtering aims at estimating the distribution of a state sequence $x_{1:N} = (x_1, x_2, \ldots, x_N)$ from a sequence of observations $y_{1:N} = (y_1, y_2, \ldots, y_N)$, given a state space model of the form

$$x_{k+1} = f(x_k, v_k) \qquad \text{or} \quad p(x_{k+1}|x_k), \quad \text{(1a)}$$

$$y_k = h(x_k, e_k) \qquad \text{or} \quad p(y_k|x_k). \qquad \text{(1b)}$$

Here, v_k denotes process noise, and e_k is the measurement noise. The stochastic variables v_k, e_k for all k and x_0 are assumed mutually independent, with known distributions p_v, p_e, and p_{x_0}, which are all being part of the model specification.

The particle filter (PF) works with a set of random trajectories. Each trajectory is formed recursively by iteratively simulating the model with some randomness and then updating the likelihood of each trajectory based on the observation. In words, we first evaluate the set of particles at hand by comparing how well they predict the current observation. In this way, the particles are assigned a weight. We keep the particles with large weight and throw away the particles with small weight, using a stochastic resampling procedure. After this step, we get a smaller set of particles, where many particles have several replicas. We then simulate each particle to the next observation time using the dynamical model. After this prediction step, all particles will be unique (because they are based on different realizations of the process noise). Below, the basic algorithm (sometimes called bootstrap PF or sequential importance resampling (SIR) PF) is summarized.

- Define a set of random states (particles) by sampling $x_0^{(i)} \sim p_{x_0}(x_0)$.
- Iterate in $k = 0, 1, \ldots$:
  1 Measurement update: Compute the weight $\omega_k^{(i)} = p_e(y_k - h(x_k^{(i)}))$ and normalize so $\sum_{i=1}^{N} \omega_k^{(i)} = 1$.

  2 Resampling: Resample each particle with probability $\omega_k^{(i)}$.
  3 Time update: Simulate one time step by taking $v_k^{(i)} \sim p_v(v_k)$ and then set $x_{k+1}^{(i)} = f(x_k^{(i)}, v_k^{(i)})$.

The main design parameter here is the number N of particles. A common trick to make the filter more robust is to increase the variance of p_v and p_e above. This is called dithering (or jittering) and is a practical way to get more robust nonlinear filters.

To illustrate some of the aspects and for later reference, a simple example will be introduced.

Example: First-Order Linear Gaussian Model

The Kalman filter (KF) provides the posterior distribution in an analytical form for linear Gaussian models and is thus suitable for evaluations and comparisons. A linear Gaussian model looks like

$$x_{k+1} = F x_k + v_k, \quad v_k \sim \mathrm{N}(0, Q). \quad \text{(2a)}$$

$$y_k = H x_k + e_k, \quad e_k \sim \mathrm{N}(0, R), \quad \text{(2b)}$$

$$x_0 \sim \mathrm{N}(\mu_0, P_0), \qquad\qquad \text{(2c)}$$

We will use the scalar case for the illustrations, and the figures that follow are based on $F = 0.9$, $H = 1$, $Q = 1$, $R = 0.01$, $P_0 = 1$. The particle filter in the scalar case simplifies to the Matlab algorithm in Table 1. Figure 1 compares the sample-based representation of the PF with the Gaussian distribution provided by the KF for the first two time steps. This shows how well the marginal distribution $p(x_k|y_{1:k})$ is approximated by the samples $x_k^{(i)}$ from the PF. A rule of thumb is that 30 samples are needed to approximate a univariate Gaussian distribution. As will be discussed later, the number of samples is effectively only 10 here, which explains the small deviation of the Gaussian functions.

To illustrate the fundamental depletion problem in the PF, the set of trajectories $x_{1:k}^{(i)}$ that

Particle Filters, Fig. 1 Set of samples $\{x_k^{(i)}\}_{i=1:N}$ compared to first a Gaussian approximation of the particles (*blue*) and second to the true posterior distribution provided by the Kalman filter (*green*)

approximates the posterior (smoothing) distribution $p(x_k|y_{1:k})$ is illustrated in Fig. 2. The upper plot shows a case where the trajectories are all the same initially. The behavior in the upper plot is typical for the basic particle filter in cases where the measurements are more informative than the state transition model (small measurement noise, $R < Q$). The lower plot shows a particle filter that is working better, and the modification is explained in the following section.

Proposal Distributions

The time update in the basic PF predicts particles in step 4 according to the dynamic model. The most general derivation of the particle filter allows for sampling from a more general proposal (also called importance) distribution. This proposal distribution can be any function that can be sampled from, and it can depend on both the previous state and the current measurement. From a filtering perspective, it may appear as
Particle Filters, Fig. 2 Set of trajectories $\{x^{(i)}_{1:10} - x_{1:10}\}_{i=1:N}$ for two different proposal distributions, one bad one (prior) leading to particle depletion and one good

one (likelihood). Note that the smoothing distribution $p(x_k|y_{1:10})$ can be approximated with the set of particles $\{x^{(i)}_k\}_{i=1:N}$ using the marginalization principle

"cheating" to look at the next measurement when doing the time update, but one has to look at a full cycle of the iteration scheme.

If a proposal distribution of the functional form $q(x_k|x_{k-1}, y_k)$ is used, then steps 1 and 3 have to be modified as follows:

1 *Weight update:* Time and measurement updates:

$$w^{(i)}_{k|k-1} \propto w^{(i)}_{k-1|k-1} \frac{p(x^{(i)}_k|x^{(i)}_{k-1})}{q(x^{(i)}_k|x^{(i)}_k, y_k)}, \quad (3a)$$

$$w^{(i)}_{k|k} \propto w^{(i)}_{k|k-1} p(y_k|x^{(i)}_k). \quad (3b)$$

3 *Prediction:* Generate samples from the proposal

$$x^{(i)}_{k+1} \sim q(x_{k+1}|x^{(i)}_k, y_{k+1}) \quad (3c)$$

The most natural proposal distributions are the following:

- The prior $q(x_{k+1}|x^{(i)}_k, y_{k+1}) = p(x_{k+1}|x^{(i)}_k)$, as used in the basic PF.
- The likelihood $q(x_{k+1}|x^{(i)}_k, y_{k+1}) \propto p(y_{k+1}|x_{k+1})$. For the model (2), the proposal becomes $N(y_k/h, R_k/h^2)$.
- The optimal (minimizing weight variance) choice $q(x_{k+1}|x^{(i)}_k, y_{k+1}) \propto p(y_{k+1}|x_{k+1}) p(x_{k+1}|x^{(i)}_k)$. For the model (2), the optimal proposal is provided by one cycle of the Kalman filter, initialized with the particle $x^{(i)}_k$.

The optimal proposal keeps the weights constant, and this would in theory avoid depletion, where depletion is interpreted as excessive weight variance. Figure 2 compares the set of trajectories for the prior and likelihood proposals, respectively. Apparently, the likelihood proposal is to prefer here, since it suffers less from depletion in the particle history. The practical limitation with the last two alternatives is that one has to be able to sample from the likelihood, so in practice there needs to be more measurements than states in the model.
Particle Filters, Fig. 3 The efficient number of particles $N_{\mathrm{eff}}(k)/N$ for prior proposal (*blue*) and likelihood proposal (*green*) ($N = 1{,}000$)

Adaptive Resampling

Resampling is crucial to avoid depletion. Without resampling, all trajectories except for one will get zero weight quite quickly. However, there is no need to resample at every iteration. Actually, resampling increases the weight variance, which is undesired. The question is how to decide if resampling is needed. The efficient number of particles estimated as

$$N_{\mathrm{eff}}(k) = \frac{1}{\sum_{i=1}^{N} \left(w_{k|k}^{(i)} \right)^2}, \qquad (4)$$

is one suitable indicator. If all particles have the same weight $w_{k|k}^{(i)} = 1/N$, then $N_{\mathrm{eff}}(k) = N$. Conversely, if one weight is one and all other zero, then $N_{\mathrm{eff}}(k) = 1$. Thus, N_{eff} can be interpreted as a measure of how many particles that actually contribute to the solution.

Figure 3 shows the evolution of $N_{\mathrm{eff}}(k)$ for prior and likelihood proposals, respectively. With resampling in every iteration, the likelihood pro-

posal performs very well with $N_{\mathrm{eff}}(k) \approx N$, while the prior proposal effectively uses only 10 % of the particles. Thus, $N_{\mathrm{eff}}(k)$ is a good indicator of the quality of the proposal distribution.

In Fig. 1, $N = 100$ so effectively 10 samples are contributing to the Gaussian approximation, which as mentioned before is too small a number to get a good result.

As a comparison, Fig. 3 also shows N_{eff} if resampling is never used, then $N_{\mathrm{eff}}(k)$ normally decreases over time. The likelihood proposal does not decrease as fast as the prior proposal, and for this very short data sequence resampling is really not needed at all.

In summary, resampling increases weight variance and decreases the performance of the filter. On the other hand, without resampling the effective number of particles converges monotonously to only one. So, the idea of adaptive resampling is natural. The key idea is to resample only if the effective number of particles is small. The usual rule of thumb is that resampling is needed if $N_{\mathrm{eff}}(k) < 2N/3$.

Resampling was the main contribution in Gordon et al. (1993) to get a working algorithm.

Marginalization

The posterior distribution approximation provided by the particle filter converges with the number of particles. In theory, the convergence rate is g_k/N, where g_k is a polynomial function in time k. In practice, it appears that the required number of particles increases very quickly with state dimension. Unless a very good proposal distribution is found, the practical limit for the state dimension is around 3–4 as a rough rule of thumb.

For applications with a large number of states, one can in many cases still use the particle filter. The idea is to find a linear Gaussian substructure in the model and then divide the state vector x_k into two parts: x_k^l for the states that appear linearly and x_k^n for the remaining states. Bayes rule provides the factorization

$$p(x_k^l, x_{1:k}^n | y_{1:k}) = p(x_k^l | x_{1:k}^n, y_{1:k}) p(x_{1:k}^n | y_{1:k}) \tag{5}$$

With a linear Gaussian substructure for x_k^l, given the whole trajectory $x_{1:k}^n$, then the Kalman filter applies and provides a Gaussian distribution for the first factor in (5). The second factor is resolved using a marginalization procedure so that the particle filter can be applied.

The bottom line is that each particle is associated with one Kalman filter. The method is called Rao-Blackwellized particle filter, or marginalized particle filter, in literature.

Illustrative Application: Navigation by Map Matching

A nontrivial application where the PF solves a nonlinear filtering problem, where Kalman filter-based approaches would fail, is described in Forssell et al. (2002). The problem is to compute a robust estimate of the position of a car, without using infrastructure such as cellular networks or satellites. The approach is based on measuring wheel speeds on one axle and from that dead reckon a nominal trajectory using standard odometric formulas. A road map is then used as a measurement, to rule out impossible or unlikely maneuvers. There is no numeric measurement y_k in this approach, but the likelihood $p(y_k|x_k)$ in the model (1b) is large when x_k corresponds to a road position and decays quickly to zero outside the road network. Figure 4 illustrates the particle cloud gradually focuses around the true position with time. In particular, the number of modes in the posterior distributions is rather high initially, but decreases over time, in particular after each turn.

The particle filter is sometimes believed to be too computer intensive for real-time applications. As described in Forssell et al. (2002), this demonstrator implemented a particle filter on a pocket computer anno 2001 with $N = 15,000$ particles running in 10 Hz. Thus, the computational complexity of the particle filter should not be overemphasized in practice.

Summary and Future Directions

The particle filter can be seen as a black-box solution to the nonlinear filtering problem, where any nonlinear dynamical model with arbitrary noise distributions can be plugged in. The main tuning parameter is the number of particles, and the PF will work in theory if this number is large enough. In practice, there are many tricks the user has to be aware of to mitigate the curse of dimensionality (depletion) that occurs for large state spaces (more than three) or long time sequences (more than a couple of samples). One engineering trick is dithering, to increase the variance in the involved noise distributions from their nominal values. More theoretical ways to mitigate depletion include clever choices of proposal distributions to sample from and marginalization (to solve a subset of the estimation problem with a Kalman filter).

Current and future research directions include the issues above. A further trend concerns the related smoothing problem, which is
Particle Filters, Fig. 4 Car navigation using wheel speed and a street map. The figures illustrate of how the particle representation of the position posterior distribution of position (course state is now shown) improves over time. After four turns, the posterior is essentially unimodal, and a position marker can be shown. The *circle* denotes GPS position, which is only used for comparison. (**a**) After first turn. (**b**) After second turn. (**c**) After third turn. (**d**) After fourth turn

interesting in itself, but which has turned out to be instrumental in joint state and parameter estimation problems. There are also many attempts to make the particle filter more robust, including ideas of filter banks and invoking a second layer of sampling algorithms to implement the proposal distribution. There is also a trend to use the particle filter as a computational engine for more complex problems, such as the simultaneous localization and mapping (SLAM) problem, and to approximate the probability hypothesis density (PHD) for multi-sensor multi-target tracking. Finally, there are a large number of papers reporting on applications in traditional as well as new disciplines.

Abstract

Perturbation analysis (PA) is a systematic methodology for estimating the sensitivities (gradient) of performance measures in discrete event systems (DES) with respect to various model or control parameters of interest. PA takes advantage of the special structure of DES sample realizations and is based entirely on observable system data. In particular, it does not require knowledge of the stochastic characterizations of the random processes involved and is simple to implement in a nonintrusive manner. PA estimators, therefore, enable implementations for real-time control in addition to off-line optimization. The article presents the main ideas and statistical properties of PA techniques for both DES and recent generalizations to stochastic hybrid systems (SHS), especially for the simplest class of sensitivity estimators known as infinitesimal perturbation analysis (IPA).

Keywords

Gradient estimation; Sample-path techniques; Sensitivity analysis; Stochastic flow models; Queueing networks

Introduction

Sensitivity analysis is an essential component of the system design process in a wide variety of application areas. In essence, it provides quantitative variations of performance metrics resulting from possible perturbations in design set points and, hence, can be used in *optimization and control* as well as provide measures of performance robustness. *Perturbation analysis* (PA) is a systematic technique for computing sample-based sensitivity estimators of performance metrics in discrete event systems (DES) by using the special properties of their sample realizations. The effectiveness of such estimators (e.g., unbiasedness) depends on the characteristics of the DES to which PA is applied and on the specific performance metric of interest. The purpose of this article is to present and explain some of the main ideas and fundamental techniques of PA.

Figure 1 depicts an abstract schematic where the operation of a stochastic system depends on a parameter θ that is chosen from a given set Θ. Let $J(\theta)$ be an expected value performance function of the system, and suppose that $J(\theta) = E\big[L(\theta)\big]$, where $E\big[\,\cdot\,\big]$ denotes expectation and $L(\theta)$ is a sample realization computable from a sample path of the system. In many situations $J(\theta)$ lacks a closed-form expression, and its sample realization, $L(\theta)$, provides the most practical way for its estimation. Applications of sensitivity analysis often concern the effects of perturbations in the parameter θ on the sample realization $L(\theta)$. Denoting such perturbations by $\Delta\theta$, their effects can be characterized by the difference term $L(\theta + \Delta\theta) - L(\theta)$. PA provides such difference terms from the *same* sample path that was used for computing $L(\theta)$. Furthermore, if $\theta \in R^n$ and the function $L(\cdot)$ is differentiable, then PA can compute the gradient term $\nabla L(\theta)$

**Perturbation Analysis of Discrete Event Systems, Fig. 1** Framework for perturbation analysis (PA)

from the same sample path. These sample path-based sensitivities can be used, under suitable conditions, to estimate the quantities $J(\theta + \Delta\theta) - J(\theta)$ and $\nabla J(\theta)$, respectively.

The PA theory was pioneered by Yu-Chi Ho who led its eventual development by his own group and other researchers over two decades. The early works were motivated by optimal resource management problems in manufacturing and concerned the effects of buffer allocation on throughput in transfer lines (Ho and Cassandras 1983; Ho et al. 1979). Subsequently PA was developed in the setting of queueing networks by virtue of their wide use as models in applications. In this setting, typically θ is a set point parameter affecting service times, inter-arrival times, routing fractions, buffer sizes, and various flow control laws; $J(\theta)$ is an expected value performance metric like average delay, throughput, and loss; and $L(\theta)$ is a sample realization of $J(\theta)$. The special structure of sample paths of queueing networks often yields simple PA algorithms for the difference terms $L(\theta + \Delta\theta) - L(\theta)$, as well as the gradient term $\nabla L(\theta)$, from the common sample path. The PA techniques for computing $L(\theta + \Delta\theta) - L(\theta)$ are collectively referred to as *finite perturbation analysis* (FPA), while those for computing $\nabla L(\theta)$ are called *infinitesimal perturbation analysis* (IPA) (Ho et al. 1983). Much of the development of PA has focused on IPA, rather than FPA, due to its greater simplicity and natural use in optimization, and, hence, it will be the focal point of this article. For comprehensive expositions of PA and its various techniques, please see Ho and Cao (1991), Glasserman (1991), and Cassandras and Lafortune (2008).

The purpose of the IPA gradient, $\nabla L(\theta)$, is to estimate $\nabla J(\theta)$. This, however, is only useful as long as $\nabla L(\theta)$ is an unbiased realization of $\nabla J(\theta)$, namely,

$$E\big[\nabla L(\theta)\big] = \nabla E[L(\theta)] = \nabla J(\theta),$$

and in this case it is said that *IPA is unbiased* (Cao 1985). Since $J(\theta) = E\big[L(\theta)\big]$, unbiasedness means the commutativity of the operators of differentiation with respect to θ and integration (expectation) in the probability space, and this is

closely related to the condition that, w.p.1, the random function $L(\theta)$ is continuous throughout Θ. As a matter of fact, the two conditions are practically synonymous. However, shortly after the emergence of IPA, it became apparent that in many queueing models of interest, $L(\theta)$ is not continuous and, hence, IPA is not unbiased (Heidelberger et al. 1988). Subsequently various techniques to overcome this problem were explored, including the so-called cut and paste of the sample paths and re-parametrization of the underlying probability space via statistical conditioning. For a more comprehensive coverage of such techniques, please see Cassandras and Lafortune (2008) and references therein. These techniques can yield unbiased gradient estimators in principle but often at the expense of prohibitive computing costs. Recently an alternative approach has emerged, based on *stochastic flow models* (SFM) that are comprised of fluid queues (Cassandras et al. 2002). It extends, significantly, the class of models and problems where IPA is unbiased and has the added advantage of yielding very simple gradient estimators.

The following sections of this article present IPA in the general setting of DES, explain the limits of its scope in queueing models, describe alternative PA techniques for extending those limits, present the SFM approach, and conclude with some thoughts on future research directions.

DES Setting for IPA

IPA can be applied to any DES modeled as a stochastic timed automaton, defined in Cassandras and Lafortune (2008) and discussed in ▶ Models for Discrete Event Systems: An Overview. Briefly, a stochastic timed automaton is a sextuple $(\mathcal{E}, \mathcal{X}, \Gamma, p, p_0, G)$, where $\mathcal{E}$ is an event set, $\mathcal{X}$ is a state space, and $\Gamma(x) \subseteq \mathcal{E}$ is the set of feasible events when the state is x, defined for all $x \in \mathcal{X}$. The initial state is drawn from $p_0(x) = P[X_0 = x]$. Subsequently, given that the current state is x, with each feasible event $i \in \Gamma(x)$, we associate a clock value Y_i, which represents the time until event i is to occur. Thus, comparing all such clock values, we identify the

triggering event $E' = \arg\min_{i \in \Gamma(x)}\{Y_i\}$, where $Y^* = \min_{i \in \Gamma(x)}\{Y_i\}$ is the inter-event time (the time elapsed since the last event occurrence). To simplify the notation we define $e' := E'$. Thus, with e' determined, the state transition probabilities $p(x'; x, e')$ are used to specify the next state x'. Finally, the clock values are updated: Y_i is decremented by Y^* for all i (other than the triggering event) which remain feasible in x', while the triggering event (and all other events which are activated upon entering x') is assigned a new lifetime sampled from a distribution G_i. The set $G = \{G_i : i \in \mathcal{E}\}$ defines the stochastic clock structure of the automaton.

Let $T_{\alpha,n}$ denote the nth occurrence time of event $\alpha \in \mathcal{E}$, and let $V_{\alpha,n}$ denote a realization of the lifetime event distribution G_α such that $V_{\alpha,n} = T_{\alpha,n} - T_{\beta,m}$ for some (any) event $\beta \in \mathcal{E}$ and $m \in \{1, 2, \ldots\}$. One can then always write $T_{\alpha,n} = V_{\beta_1,k_1} + \ldots + V_{\beta_s,k_s}$ for some s. Let us now consider a parameter $\theta \in R$ which can only affect one or more of the event lifetime distributions $G_\alpha(x; \theta)$; in particular, θ does not affect the state transition mechanism. The case where $\theta \in R^n$ can be handled in similar ways, but the one-dimensional case permits us to use the derivative notation rather than the gradient symbol, which simplifies the presentation. Viewing lifetimes as functions of θ, $V_{\alpha,k}(\theta)$, it can be shown (under mild technical conditions, see Glasserman (1991)) that

$$\frac{dV_{\alpha,k}}{d\theta} = -\frac{[\partial G_\alpha(x; \theta)/\partial\theta]_{(V_{\alpha,k},\theta)}}{[\partial G_\alpha(x; \theta)/\partial x]_{(V_{\alpha,k},\theta)}}, \quad (1)$$

where the subscript $(V_{\alpha,k}, \theta)$ indicates that the corresponding derivative of G_α is evaluated at the point $(V_{\alpha,k}, \theta)$. This describes how a perturbation in θ *generates* a perturbation in the associated event lifetime $V_{\alpha,k}$. Such a perturbation can now *propagate* through the DES to affect various event occurrence times according to the dynamics prescribed by the stochastic timed automaton. Event time derivatives $dT_{\alpha,n}(\theta)/d\theta$ are given by

$$\frac{dT_{\alpha,n}}{d\theta} = \sum_{\beta,m} \frac{dV_{\beta,m}}{d\theta}\eta(\alpha, n; \beta, m), \quad (2)$$

where $\eta(\alpha, n; \beta, m)$ is a triggering indicator taking values in $\{0, 1\}$ so that $\eta(\alpha, n; \beta, m) = 1$ if the nth occurrence of event α is triggered by the mth occurrence of β, $\eta(\alpha, n; \alpha, n) = 1$ for all $\alpha \in \mathcal{E}$, $\eta(\alpha, n; \beta', m') = 1$ if $\eta(\alpha, n; \beta, m) = 1$ and $\eta(\beta, m; \beta', m') = 1$, and $\eta(\alpha, n; \beta, m) = 0$ otherwise.

This leads to a general-purpose algorithm for evaluating event time derivatives along an observed sample path (see Algorithm 1) of a DES modeled as a stochastic timed automaton. In particular, we define a perturbation accumulator, Δ_α, for every event $\alpha \in \mathcal{E}$. The accumulator Δ_α is updated at event occurrences in two ways: (i) It is incremented by $dV_\alpha/d\theta$ whenever an event α occurs, and (ii) it is coupled to an accumulator Δ_β whenever an event β (possibly $\beta = \alpha$) occurs that activates an event α. No particular stopping condition is specified, since this may vary depending on the problem of interest.

Sample Function Derivatives. Since many sample performance functions $L(\theta)$ of interest can be expressed in terms of event times $T_{\alpha,n}$, we can use (2) and Algorithm 1

Algorithm 1 General-purpose IPA algorithm for stochastic timed automata

1. Initialization
   If event α is feasible at x_0: $\Delta_\alpha := dV_{\alpha,1}/d\theta$
   Else, for all other $\alpha \in \mathcal{E}$: $\Delta_\alpha := 0$
2. Whenever event β is observed
   If event α is activated with new lifetime V_α:

   2.1. Compute $dV_\alpha/d\theta$ through (1)
   2.2. $\Delta_\alpha := \Delta_\beta + dV_\alpha/d\theta$

---

in order to obtain derivatives of the form $dL(\theta)/d\theta$. As an example, a large class of such functions is of the form

$$L_T(\theta) = \int_0^T C(x(t, \theta))dt,$$

where $C(x(t, \theta))$ is a bounded cost associated with operating the system at state $x(t, \theta)$. Then,

$$\frac{dL_T}{d\theta} = \sum_{k=1}^{N(T)} \frac{dT_k}{d\theta}[C(x_{k-1}) - C(x_k)],$$

where $N(T)$ counts the total number of events observed in $[0, T]$ and x_k is the state remaining fixed in any interval (T_k, T_{k+1}) with $T_k = T_{\alpha,n}$ for some $\alpha \in \mathcal{E}$, $n = 1, 2, \ldots$.

Estimation of Performance Measure Derivatives. Using $dL_T(\theta)/d\theta$ from above, we can obtain unbiased estimates of $dJ/d\theta$ if the following condition holds:

$$\frac{dJ(\theta)}{d\theta} = E\left[\frac{dL_T(\theta)}{d\theta}\right].$$

As mentioned earlier, this key condition is closely related to the continuity of the sample performance functions. A discontinuity often is caused by a swap in the order of two events that results from small variations in θ and yields different future state trajectories. However, it is possible that the future state trajectory following the occurrence of the two events is invariant under their order, and in this case the two events are said to *commute*. This commuting condition, defined by Glasserman, was shown to be identical, under broad assumptions, to the continuity of the sample functions $L(\theta)$ and, hence, to the unbiasedness of IPA (Glasserman 1991).

The main ideas discussed in this section will next be illustrated on a simple queue.

Queueing Example

Consider the IPA gradient (derivative) of the expected sojourn time (delay) in a GI/G/1 queue with respect to a real-valued parameter of its arrival process. Assume that the queue is empty at time $t = 0$, and it serves its customers according to the order of their arrivals. Let us denote by a_k, $k = 1, 2, \ldots$, the arrival times, and by s_k, $k = 1, 2, \ldots$, the service times of consecutive customers. Furthermore, we denote by v_k, $k = 1, 2, \ldots$, the kth inter-arrival time, namely, $v_k = a_k - a_{k-1}$, where $a_0 := 0$. Observe that the queue is a stochastic timed automaton as defined earlier,

with event space {arrival, departure}, state space {0, 1, ...} representing the queue's occupancy, and feasible event set {arrival} when $x = 0$ and {arrival, departure} when $x > 0$.

Let $\theta \in R$ is a parameter of the distribution of the inter-arrival times, and, hence, the realizations of v depend on θ in a functional manner. For example, if the arrival process is Poisson and θ is its rate, then a realization of the inter-arrival times has the form $v = -\theta \ln(1 - \omega)$, where $\omega \in [0, 1]$ is a uniform variate. To emphasize the dependence of v on θ, we denote it by $v(\theta)$, while its dependence on ω is implicit. Similarly, the arrival times depend on θ and, hence, are denoted by $a_k(\theta)$, but the service times s_k do not depend on θ. The departure time of the kth customer and its delay depend on θ and are denoted by $d_k(\theta)$ and $D_k(\theta)$, respectively. The forthcoming paragraphs discuss the derivatives of these functions with respect to θ; we use the prime symbol to indicate such derivatives in order to simplify the notation.

Define the sample performance function

$$L_N(\theta) := N^{-1} \sum_{k=1}^{N} D_k(\theta)$$

for a given $N > 0$. Under stability conditions, with probability 1 (w.p.1), $\lim_{N \to \infty} L_N(\theta) = J(\theta)$, where $J(\theta)$ denotes the mean of the delay's stationary distribution. The role of IPA is to estimate $J'(\theta)$ via the sample derivative $L_N'(\theta)$, and this is justified as long as $\lim_{N \to \infty} L_N'(\theta) = J'(\theta)$ w.p.1. In this case, IPA is said to be *strongly consistent*. In contrast, unbiasedness pertains to the performance function $J_N(\theta) := E[L_N(\theta)]$ and means that $E[L_N'(\theta)] = J_N'(\theta)$. The concepts of strong consistency and unbiasedness are closely related except that the latter concerns finite-horizon processes while the former pertains to stationary distributions in steady state. Both concepts have been extensively investigated in recent years: strong consistency in the setting of Markov chains and Markov decision processes Cao (2007) and unbiasedness in the context of stochastic hybrid systems, as will be described in the sequel. We will focus the rest of the discussion on the issue of unbiasedness.

Since $L_N(\theta) = N^{-1} \sum_{k=1}^{N} D_k(\theta)$, its IPA derivative is $L_N'(\theta) = N^{-1} \sum_{k=1}^{N} D_k'(\theta)$, and since $D_k(\theta) = a_k(\theta) - d_k(\theta)$, it follows that $D_k'(\theta) = a_k'(\theta) - d_k'(\theta)$. The last two derivative terms are computable via the following recursive procedures. First, $a_k(\theta) = a_{k-1}(\theta) + v_k(\theta)$, and, hence,

$$a_k'(\theta) = a_{k-1}'(\theta) + v_k'(\theta).$$

The term $v_k'(\theta)$ has to be obtained directly from the realization of v, and this often is possible since such realizations depend functionally on θ; for instance, in the previous example, $v = -\theta \ln(1 - \omega)$ and, hence, $v'(\theta) = -\ln(1 - \omega)$. Next, $d_k(\theta)$ is given by the Lindley equation

$$d_k(\theta) = \max \{a_k(\theta), d_{k-1}(\theta)\} + s_k,$$

and, therefore, denoting by ℓ_k the index of the customer that started the busy period containing customer k, we have that

$$d_k'(\theta) = a_{\ell_k}'(\theta).$$

From these recursive relations it follows that $D_k'(\theta) = 0$ if customer k starts a busy period and $D_k'(\theta) = -\sum_{i=\ell_k+1}^{k} v_i'(\theta)$ if customer k does not start a busy period.

These equations shed light on the structure of IPA in a general class of queueing networks. First there is the *perturbation generation*, namely, the sampling of derivative (gradient) terms directly from the sample sequence of variates (ω) which defines the sample path; that was $v'(\theta)$ in the above example. These terms drive the recursive equations that yield the IPA derivatives. The recursive equations often are based on the tracking of certain events such as the start of busy periods or idle periods, and the process of tracking the derivatives through them is referred to as *perturbation propagation*. In the above example it is obvious how the perturbation propagation tracks the busy periods at the queue. Furthermore, in a network setting, the perturbations can propagate from one queue to the next in a natural fashion. For instance, suppose that customers departing

$v_{1,k}(\theta)$

$v_{2,m}$
Perturbation Analysis of Discrete Event Systems, Fig. 2 Queue with two customer classes

from the queue analyzed above enter a second queue. Then the derivative terms $d_k'(\theta)$ of the upstream queue act as the derivative terms $a_k'(\theta)$ of the downstream queue. This structure of perturbations' generation and propagation through the tracking of busy periods and other events often yields simple recursive algorithms for computing the IPA derivatives.

Concerning the issue of unbiasedness, it is clear that in the above example, the sample function $L_N(\theta)$ is continuous in θ and, hence, IPA is unbiased. However, in many systems of interest the IPA, derivative is biased. For example, consider the two-input, single-server queue shown in Fig. 2, where customers are served according to their arrival order regardless of source. Suppose that θ is a parameter of the upper arrival process, but not of the lower arrival process, and denote the respective inter-arrival times of the input streams by $v_{1,k}(\theta)$, $k = 1, 2, \ldots$, and $v_{2,m}$ $m = 1, 2, \ldots$, as indicated in the figure. Furthermore, let $d_{1,k}(\theta)$ denote the departure time from the queue of the kth customer that came from the upper source, and let $d_{2,m}(\theta)$ denote the departure time from the queue of the mth customer that came from the lower source. Similarly, let $D_{1,k}(\theta)$ and $D_{2,m}(\theta)$ be the delays of the kth customer from the upper source and the mth customer from the lower source, respectively. Lastly, in analogy with the previous example, consider the sample performance functions $L_{1,N}(\theta) := N^{-1} \sum_{k=1}^{N} D_{1,k}(\theta)$ and $L_{2,N}(\theta) := N^{-1} \sum_{m=1}^{N} D_{2,m}(\theta)$.

The IPA derivatives $L_{1,N}'(\theta)$ and $L_{2,N}'(\theta)$ have quite similar expressions to those derived earlier, but they are not unbiased. To see this point, suppose that $v_{1,k}(\cdot)$ is a monotone increasing function of θ, and consider the functions $a_{1,k}(\theta)$, $d_{1,k}(\theta)$, and $d_{2,k}(\theta)$ for a common sample path. Suppose that at some point $\bar{\theta}$ the order of arrivals of the nth customer from the upper source

and the mth customer from the lower source is swapped. Then the service order of these customers will be swapped as well, inducing discontinuities in $d_{1,k}(\theta)$ and $d_{2,m}(\theta)$ at the point $\theta = \bar{\theta}$. Consequently, the sample performance functions $L_{1,N}(\theta)$ and $L_{2,N}(\theta)$ also will be discontinuous at $\theta = \bar{\theta}$, and hence, their IPA derivatives are biased. Furthermore, if the queue is a part of a network and its output process directs customers to other queues, then the discontinuities in the various traffic processes will propagate downstream.

The causes of biasedness in queueing networks include multiple customer classes, non-Markovian routing, and loss (spillover) due to finite buffers. This leaves out a limited class of networks where IPA can be unbiased and, hence, useful in applications. The following sections describe various approaches to overcome this problem.

IPA Extensions

When IPA fails (because the commuting condition is violated or a sample function exhibits discontinuities in θ), one can still use the PA approach to derive unbiased performance sensitivity estimates. There are two ways to accomplish this: (i) by modifying the stochastic timed automaton model so that IPA is "made to work" and (ii) by paying the price of more information collected from the observed sample path, in which case, the same essential PA philosophy can lead to unbiased and strongly consistent estimators, but these are no longer as simple as IPA ones. Regarding (i), the main idea here is that there may be more than one way to construct (statistically equivalent) sample paths of a stochastic DES, and while one way leads to discontinuous sample functions $L(\theta)$, another does not; a variety of such ways is provided in Cassandras and Lafortune (2008). Regarding (ii), the methodology of *smoothed perturbation analysis* (SPA) (Gong and Ho 1987) provides a generalization of IPA in which more information is extracted from a DES sample path in order to gain some knowledge about the magnitude of jumps in $L(\theta)$.

P

The main idea of SPA lies in the "smoothing property" of conditional expectation. If we are willing to extract information from a sample path and denote it by $\mathcal{Z}$, called the *characterization* of the sample path, then we can evaluate, not just the sample function $L(\theta)$, but also the conditional expectation $E\big[L(\theta) \mid \mathcal{Z}\big]$ (provided we have some distributional knowledge based on which this expectation can be evaluated). This can result in a much smoother function of θ than $L(\theta)$. Thus, starting with the condition for an IPA estimator to be unbiased,

$$\nabla J(\theta) = E\big[\nabla L(\theta)\big],$$

we rewrite the left-hand side above as shown below, replacing $J(\theta) = E\big[(L(\theta)\big]$ by the expectation of a conditional expectation:

$$\nabla J(\theta) = \nabla E\big[L(\theta)\big] = \nabla E\big[E[L(\theta) \mid \mathcal{Z}]\big], \tag{3}$$

where the inner expectation is a conditional one and the conditioning is on the characterization $\mathcal{Z}$. Treating $E\big[L(\theta) \mid \mathcal{Z}\big]$ as the new sample function, we expect it to be "smoother" than $L(\theta)$, and, in particular, continuous in θ. Then, under some additional conditions (comparable to those made in the development of IPA) the interchange of differentiation and expectation in (3) can be justified:

$$\nabla J(\theta) = E\big[\nabla E[L(\theta) \mid \mathcal{Z}]\big].$$

Letting $L_{\mathcal{Z}}(\theta) := E\big[L(\theta) \mid \mathcal{Z}\big]$, the SPA estimator of $\nabla J(\theta)$ is

$$[\nabla J(\theta)]_{\text{SPA}} = \nabla L_{\mathcal{Z}}(\theta). \tag{4}$$

Naturally, the idea is to minimize the amount of added information represented by $\mathcal{Z}$, since this incurs added costs we would like to avoid. The choice of the characterization $\mathcal{Z}$ generally depends on the sample function considered and the system under study.

A number of other extensions to IPA have also been developed (see Cassandras and Lafortune 2008). It is also worth mentioning that the PA approach can be applied to a parameter θ taking values from a finite set $\Theta = \{\theta_0, \theta_1, \ldots, \theta_M\}$. The theory of *concurrent estimation* and *sample path constructability* provides techniques to estimate performance measures of the DES through the process of constructing sample paths under each of $\theta_0, \theta_1, \ldots, \theta_M$; for details see Cassandras and Lafortune (2008).

SFM Framework for IPA

The stochastic flow model (SFM) framework essentially consists of fluid queues which forego the notion of the individual customer and focus instead on the aggregate flow. In such a fluid queue, traffic and service processes are characterized by instantaneous flow rates as opposed to the arrival, departure, and service times of discrete customers. The SFM qualifies as a *stochastic hybrid system* with bilayer dynamics: discrete event dynamics at the upper layer and time-driven dynamics at the lower layer. The discrete events are associated with abrupt (discontinuous) changes in traffic-flow processes, such as the boundaries of busy periods at the queues. In contrast, the time-driven dynamics describe the continuous evolution of flow rates between successive discrete events, usually by differential equations or explicit functional terms. Performance metrics that are natural to SFMs typically reflect quantitative measures of flow rates, like average throughput, buffer workload, and loss.

Due to the smoothing effects of SFMs, they appear to provide a far more natural setting for IPA than their analogous discrete queueing counterparts. Furthermore, their IPA gradients often are computable via extremely simple algorithms that are based entirely on the observed sample path. Consequently SFMs could, in principle, be implemented on the sample paths generated by an actual system rather than simulations thereof and thus be used in real-time optimization.

All of this next will be explained via a concrete example of a queue which, though simple, captures the salient features of the SFM setting for IPA. For a more comprehensive discussion, please see Cassandras et al. (2010), Wardi et al. (2010), and Yao and Cassandras (2013).
Perturbation Analysis of Discrete Event Systems, Fig. 3 Basic SFM

Consider the fluid queue depicted in Fig. 3 whose input and output flow rate processes are denoted, respectively, by $\alpha(t)$ and $\delta(t)$. The output flow process depends on the input flow process via the action of the server as well as the buffer size. The server is characterized by an instantaneous processing rate, denoted by $\beta(t)$, and the buffer size, namely, the maximum amount of fluid the buffer can hold, is denoted by c. Fluid overflow occurs when the inflow (arrival) rate exceeds the service rate while the buffer is full, and the overflow (loss) rate is denoted by $\gamma(t)$.

Suppose that $\alpha(t)$ and $\beta(t)$ are random functions defined on a suitable probability space, and assume that they are piecewise continuous and of bounded variation w.p.1. In order to describe their functional relations to $\delta(t)$ and $\gamma(t)$, we define the state variable to be the amount of fluid in the buffer (workload) and denote it by $x(t)$. The dynamics of the system evolve according to the following one-sided differential equation,

$$\frac{dx}{dt^+} = \begin{cases} 0, & \text{if } x(t) = 0 \text{ and } \alpha(t) \leq \beta(t) \\ 0, & \text{if } x(t) = c \text{ and } \alpha(t) \geq \beta(t) \\ \alpha(t) - \beta(t), & \text{otherwise}, \end{cases}$$

and $\delta(t)$ and $\gamma(t)$ are related to them via

$$\delta(t) = \begin{cases} \beta(t), & \text{if } x(t) > 0 \\ \alpha(t), & \text{if } x(t) = 0, \end{cases}$$

and

$$\gamma(t) = \begin{cases} \alpha(t) - \beta(t), & \text{if } x(t) = c \\ 0, & \text{if } x(t) < c. \end{cases}$$

Network arrangements of such fluid queues, with specified routing and control schemes, provide a rich class of SFMs.

Let $\theta \in R$ be a parameter of the inflow rate, the service rate, or a network control law; for instance, θ can be the *on* time of the flow from an off/on source, a uniform rate of the server, or the threshold level in a threshold-based flow control. Then the aforementioned traffic processes are functions of θ and t and, hence, are denoted by $\alpha(\theta; t)$, $\beta(\theta; t)$, $x(\theta; t)$, etc. Fix the parameter θ, and consider the evolution of the system over a given time horizon $[0, T]$. Performance measures of interest in applications include the average loss rate over the horizon $[0, T]$ and the average workload there which is related to the delay by Little's Law. Related to them are the sample performance functions $L_{\gamma,T}(\theta) := \int_0^T \gamma(\theta, t)dt$ and $L_{x,T}(\theta) := \int_0^T x(\theta, t)dt$; the former is called the *loss volume* and the latter, the *cumulative workload*.

To illustrate the forms of their IPA derivatives, consider the basic SFM shown in Fig. 3, and let θ be its buffer size, namely, $\theta = c$. We say that a busy period of the queue is *lossy* if it incurs some loss at any amount. Let us denote by N_T the number of lossy busy periods in the horizon $[0, T]$. Then (see Cassandras et al. 2002), the IPA derivative of the loss volume has the following form:

$$L'_{\gamma,T}(\theta) = -N_T,$$

where again we use the prime symbol to denote derivative with respect to θ. This formula amounts to a counting process and indeed it is very simple. As an example, Fig. 4 depicts a typical state trajectory derived from a sample path. It is readily seen that the first busy period is lossy while the second one is not, and therefore, $L'_{\gamma,T}(\theta) = -1$.

Concerning the cumulative workload, suppose that the queue has M lossy busy periods in the time interval $[0, T]$, and let us enumerate them by the counter $m = 1, \ldots, M$. Moreover, denote by u_m the first time the buffer becomes full in its mth lossy busy period and by v_m, the end-time of that busy period. Then (see Cassandras et al. 2002),

$$L'_{x,T}(\theta) = \sum_{m=1}^{M} (v_m - u_m).$$

In the example provided by Fig. 4, $L'_{x,T}(\theta) = v_1 - u_1$.
Perturbation Analysis of Discrete Event Systems, Fig. 4 State trajectory of the SFM

These equations for the IPA derivatives not only are very simple, but require no knowledge of the specific form of the processes $\{\alpha(t)\}$ or $\{\beta(t)\}$, their realizations, or underlying probability law. They depend only on limited information which is directly observed from the sample path and, hence, are said to be *nonparametric* or *model free*. Furthermore, they have been shown to possess considerable robustness to modeling variations that do not cause significant alterations of the busy periods of the queue. A case of interest is when the SFM formalism is used as an abstraction of a queue. Then the above IPA formulas that were derived from an analysis of the SFM can be successfully applied to sample paths that are generated from the discrete queue. This is in contrast to the IPA formulas that are derived from the discrete queue, which generally are highly biased.

All of these properties of IPA in the SFM setting, including its unbiasedness, simplicity, the nonparametric nature of its algorithms, and its robustness to model variations, have had extensions to SFM networks and systems beyond the basic model (see Cassandras et al. 2010; Wardi et al. 2010; Yao and Cassandras 2013). As mentioned above, this suggests the potential application of IPA not only in system optimization via off-line simulation but also in real-time control where the sample paths are generated from the actual system.

Summary and Future Directions

In the past 10 years, the focus of research on IPA has shifted from the setting of queueing systems to the framework of SFMs. The main reason for this shift is that IPA yields unbiased gradient estimators for a considerably richer class of networks and performance functions in the SFM setting than for their analogous queueing models. Furthermore, the algorithms for computing the IPA gradients often are nonparametric, robust to modeling variations, and very simple to compute, and, hence, they hold out promise of implementations in real-time control in addition to off-line optimization.

In analogy with the extension of the scope of IPA from queueing systems to stochastic timed automata, the SFM framework has been extended to *stochastic hybrid systems* (SHS), defined in Cassandras et al. (2010). In such systems, including SFMs, the functional description of the time-driven dynamics is changed according to the occurrence of specific events. However, whereas in SFMs these dynamics are described by explicit functional relations, in SHS they are expressed by differential equations. The aforementioned, appealing properties of IPA gradients in the SFM setting appear to have extensions to the wider context of SHS.

Future directions in the use of IPA are expected to focus on the control of high-speed large-volume networks and, more generally, the control of stochastic hybrid systems.

Institute of Advanced Study, Hong Kong University of Science and Technology, Hong Kong, China

Abstract

We introduce the theories and methodologies that utilize the special features of discrete event dynamic systems (DEDSs) for perturbation analysis (PA) and optimization of steady-state performance. Such theories and methodologies usually take different perspectives from the traditional optimization approaches and therefore may lead to new insights and efficient algorithms.

The topic discussed includes the gradient-based optimization for systems with continuous parameters and the direct-comparison-based optimization for systems with discrete policies, which is an alternative to dynamic programming and may apply when the latter fails. Furthermore, these new insights can also be applied to continuous-time and continuous-state dynamic systems, leading to a new paradigm of optimal control.

Keywords

Gradient estimation; Sample-path techniques; Sensitivity analysis; Queueing networks

Introduction

In this chapter, we introduce the theories and methodologies that utilize the special features of discrete event dynamic systems (DEDSs) for perturbation analysis (PA) and optimization of steady-state performance. Such theories and methodologies usually take different perspectives from the traditional optimization approaches and therefore may lead to new insights and efficient algorithms. Furthermore, these new insights can also be applied to continuous-time and continuous state dynamic systems, leading to a new paradigm of optimal control.

As discussed in ▶ Perturbation Analysis of Discrete Event Systems, perturbation analysis (PA) can be applied to both performance in finite-period and steady-state performance. This chapter will mainly focus on the latter and a related topic, the sensitivity-based optimization of steady-state performance of stochastic discrete event dynamic systems.

Gradient-Based Approaches

Basic Ideas

The gradient-based performance optimization of discrete event dynamic systems (DEDSs) consists of three steps:

P

1. Developing efficient algorithms to estimate the performance gradients using the special features of a DEDS
2. Studying the properties of the gradient estimates, including investigating whether they are unbiased and/or strongly consistent
3. With the gradient estimates, developing efficient optimization algorithms

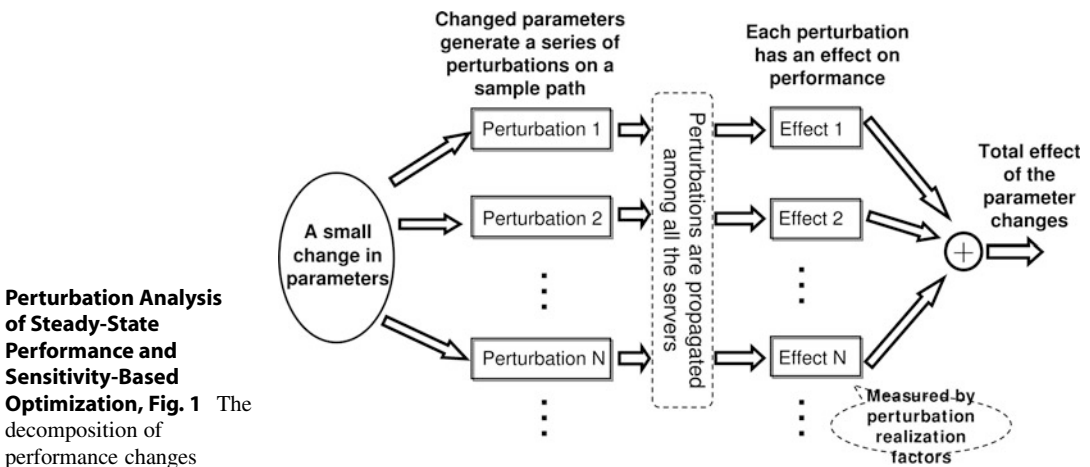
Steps 1 and 2 are referred to as PA, and Step 3 is usually done together with standard gradient-based optimization approaches, such as hill-climbing type of approaches and stochastic approximation approaches such as the Robbins-Monro algorithm (Robbins and Monro 1951).

Our focus here is on PA for steady-state performance. The main principle for estimating the gradients of steady-state performance is decomposition. In a DEDS, a small change in the value of a system parameter induces a series of changes on the system's sample path; each of such changes is called a *perturbation*. A single perturbation alone will affect the sample path and therefore affect the system performance. Such an effect is typically small, and therefore, the linear superposition usually holds. Thus, the effect of a small parameter change on the steady-state performance can be determined by summing up the effects of all the perturbations induced (or generated) by the parameter change. This principle is illustrated by Fig. 1, and it applies to many different systems with different performance criteria. Following the principle, efficient algorithms can be developed, and their strong consistency can be

proved Cao (2007). Its application to queueing systems and Markov systems will be discussed in the following two subsections.

Queueing Systems

The gradient-based approach for DEDSs starts with queueing systems, known as infinitesimal perturbation analysis (IPA), or simply PA, ▶ Perturbation Analysis of Discrete Event Systems. Queueing systems are widely used as a model for many DEDSs in literature and have very unique structural features, and PA utilizes such special features to develop fast algorithms to estimate the performance gradients.

We first give a brief explanation for the simple rules of PA of queueing systems (Ho and Cao 1983, 1991). Consider a closed Jackson network with M servers and N customers. The service times of customers at server i are exponentially distributed with service rate μ_i, $i = 1, 2, \cdots, M$. After a customer completes its service at server i, it goes to server j with a routing probability q_{ij}, $i, j = 1, 2, \cdots, M$. The service discipline is first come first served. The number of customers at server i is denoted as n_i, and the system state is denoted as $\boldsymbol{n} = (n_1, n_2, \cdots, n_M)$. The state process is $\boldsymbol{n}(t) = (n_1(t), n_2(t), \cdots, n_M(t))$ with $n_i(t)$ being the number of customers at server i at time t, $i = 1, 2, \cdots, M$, $t \geq 0$. Define T_l as the lth state transition time of the process $\boldsymbol{n}(t)$.


Perturbation Analysis of Steady-State Performance and Sensitivity-Based Optimization, Fig. 1 The decomposition of performance changes

Perturbation Analysis of Steady-State Performance and Sensitivity-Based Optimization, Fig. 2 Perturbation generation and propagation in a queueing network
Figure 2 illustrates an example of a sample path where each stair-style line represents a trajectory of the number of customers at one server, and the customer transitions among servers are indicated by dotted arrows.

An exponentially distributed service time with rate μ can be generated according to $s = -\frac{1}{\mu} \ln \zeta$, where ζ is a uniformly distributed random number in [0, 1]. Now let the service rate of a server, say server k, change from μ_k to $\mu_k + \Delta\mu_k$, $\Delta\mu_k << \mu_k$. Then the service time s will change to $s' = -\frac{1}{\mu_k + \Delta\mu_k} \ln \zeta$ (the same ζ is used for both s and s'). Thus, the perturbation of the service time induced by the change in μ_k is

$$\Delta s = s' - s \approx -\frac{\Delta\mu_k}{\mu_k} s. \qquad (1)$$

In summary, because of a small (infinitesimal) change of service rate $\Delta\mu_k$, every customer's service completion time at server k will obtain (be delayed by) a perturbation that is proportional to its original service time with a multiplier $-\frac{\Delta\mu_k}{\mu_k}$. This is the rule of *perturbation generation*.

Next, we observe that a perturbation will affect the service starting and completion times of other customers in the same server and in other servers in the network. We say a perturbation will be *propagated* through the network.

First, the perturbations generated at a server will accumulate until this server is idle. When the server enters an idle period, all its perturbations will be lost. (After the idle period, the service starting time is determined by the customer that terminates the idle period, which carries the perturbation of another server.) Second, when a customer finishes its service at server i and enters server j after an idle period of server j, server j will obtain the same amount of perturbations as server i. If server j is not idle at this time, the perturbation at server i will only affect the arrival time of this customer and will not affect any other customers/servers.

Figure 2 illustrates the perturbation generation and propagation process of a network in which the service rate of server 1 is decreased with an infinitesimal amount. Given a system sample path obtained by simulation or observation, we can record the perturbations of all servers as they are generated and propagated along the sample path. From the perturbations we can get a perturbed sample path and finally get the performance changes caused by the change in the service rate. Specifically, we have the following algorithm for the perturbations of the service completion times (if server k's service rate is perturbed).

In Step 2, we add $s_{k,l}$ as the perturbation generated, instead $-\frac{\Delta\mu_k}{\mu_k} s_{k,l}$ as indicated by (1).

Algorithm 1 Perturbation Analysis

1. *Initialization:* Set variables $\Delta_i = 0, i = 1, 2, \cdots, M$.
2. *Perturbation generation:* At the lth service completion time of server k, set $\Delta_k = \Delta_k + s_{k,l}, l = 1, 2, \cdots$, where $s_{k,l}$ is the service time of the lth customer at server k.
3. *Perturbation propagation:* If a customer from server i terminates an idle period of server j, set $\Delta_j = \Delta_i$, $i, j = 1, 2, \cdots, M$.

The factor $-\frac{\Delta \mu_k}{\mu_k}$ will be canceled when estimating performance derivatives with respect to $\Delta \mu_k$. The algorithm yields a perturbed sample path. With the original path and the perturbed path, we can estimate the original and perturbed (steady-state) throughput, then the estimates of its derivative with respect to μ_k can be obtained, and it is proved that the estimate is strongly consistent. Only a few lines need to be added in the simulation code to obtain the derivatives. Experiments show that the results are very accurate (error is around 5 %, compared with analytical results, Ho and Cao 1983).

Markov Systems

The decomposition principle shown in Fig. 1 has been applied to Markov systems (Cao 2007).

Consider an irreducible and aperiodic Markov chain $\mathbf{X} = \{X_n : n \geq 0\}$ on a finite state space $\mathcal{S} = \{1, 2, \cdots, M\}$ with transition probability matrix $P = [p(j|i)] \in [0, 1]^{M \times M}$. Let $\pi = (\pi_1, \ldots, \pi_M)$ be the vector representing its steady-state probabilities and $f = (f_1, f_2, \cdots, f_M)^T$ be the reward (or cost) vector, where "T" represents transpose. We have $Pe = e$, where $e = (1, 1, \cdots, 1)^T$ is an M-dimensional vector whose all components equal 1, and we have $\pi = \pi P$. We consider the long-term average (steady-state) performance defined as

$$\eta = E_\pi(f) = \sum_{i=1}^{M} \pi_i f_i$$

$$= \pi f = \lim_{L \to \infty} \frac{F_L}{L}, \quad w.p.1, \qquad (2)$$

where

$$F_L = \sum_{l=0}^{L-1} f(X_l).$$

Let P' be another ergodic transition probability matrix on the same state space. Suppose P changes to $P(\delta) = P + \delta Q = \delta P' + (1 - \delta)P$, with $\delta > 0$, $Q = P' - P = [q(j|i)]$, and the reward function f keeps the same. We have $Qe = 0$. The performance measure will change to $\eta(\delta) = \eta + \Delta \eta(\delta)$. The derivative of η in the direction of Q is defined as $\frac{d\eta(\delta)}{d\delta} = \lim_{\delta \to 0} \frac{\Delta \eta(\delta)}{\delta}$.

In this discrete-state Markov system, a perturbation means that the system is perturbed from one state i to another state j. For example, consider the case where $q(i|k) = \frac{1}{2}, q(j|k) = \frac{1}{2}$, and $q(l|k) = 0$ for all $l \neq i, j$. Suppose that these probabilities change to $q(i|k) = \frac{1}{2} + \delta$, $q(j|k) = \frac{1}{2} - \delta$, and $q'(l|k) = 0$ for all $l \neq i, j$. Then it may happen that at some time in the original sample path the system transits from state k to state i, but in the perturbed path it transits from state k to state j instead. In this case, we say that the change in transition probabilities induces a perturbation from i to j at this time. To study the effect of such a perturbation, we consider two independent sample paths $\mathbf{X} = \{X_n; n \geq 0\}$ and $\mathbf{X}' = \{X_n'; n \geq 0\}$ with $X_0 = i$ and $X_0' = j$; both of them have the same transition matrix P. The average effect of a perturbation from i to j, $i, j = 1, \cdots, M$, on F_L can be measured by the *perturbation realization factor* defined as

$$d(i, j) = \lim_{L \to \infty} E\left[\sum_{l=0}^{L-1} (f(X_l') - f(X_l)) | X_0 \right.$$

$$\left. = i, X_0' = j \right]. \qquad (3)$$

The matrix $D \in \mathcal{R}^{M \times M}$, with $d(i, j)$ as its (i, j)th element, is called a *realization matrix*. We can prove that D satisfies the equation (Cao 2007)

$$D - PDP^T = F, \qquad (4)$$

where $F = fe^T - ef^T$. Because $d(i, j) = -d(j, i)$, for any i, j, we may define a vector $g = (g(1), \cdots, g(M))^T$ such that

$$d(i, j) = g(j) - g(i), \qquad (5)$$

and $D = ge^T - eg^T$. g is called a *performance potential*, which can be estimated with many sample path-based algorithms, and it satisfies the Poisson equation (Cao 2007)

$$(I - P + e\pi)g = f. \qquad (6)$$

Intuitively, (3) and (5) indicate that every visit to state i contributes to F_L on the average by the amount of $g(i)$, so the effect of a perturbation from i to j is $d(i, j) = g(j) - g(i)$. Now, we consider a sample path consisting of L transitions. Among these transitions, on the average there are $L\pi_i$ transitions at which the system is at state i. After being at state i, the system jumps to state j on the average $L\pi_i p(j|i)$ times. If the transition probability matrix P changes to $P(\delta) = P + \delta Q$, then the change in the number of visits to state j after being at state i is $L\pi_i q(j|i)\delta = L\pi_i[p'(j|i) - p(j||i)]\delta$. This contributes a change of $\{L\pi_i[p'(j|i) - p(j|i)]\delta\}g(i)$ to F_L. Thus, the total change in F_L due to the change of P to $P(\delta)$ is

$$\Delta F_L = \sum_{i,j=1}^{M} L\pi_i[p'(j|i) - p(j|i)]\delta g(i)$$
$$= L(\pi Q g)\delta.$$

Finally, we have

$$\frac{d\eta}{d\delta} = \lim_{\delta \to 0} \frac{1}{\delta}\frac{\Delta F_L}{L} = \pi Q g = \pi(P' - P)g. \qquad (7)$$

If the reward function also changes from f to $f(\delta) = f + \delta(f' - f)$, then (7) becomes

$$\frac{d\eta}{d\delta} = \pi[(P'g + f') - (Pg + f)]. \qquad (8)$$

Further Works

The ideas described in the previous subsections may stimulate new research topics in theoretical analysis, estimation algorithms, and applications. Here we can only give a very brief review for some of them.

1. There is a large literature on whether the PA-based derivative estimates are unbiased (finite period) and/or strongly consistent (steady state). This was first formulated in Cao (1985) and was further discussed in Heidelberger et al. (1988). By now, there have been extensive studies in this direction: proving the unbiasedness or consistency for various systems and modifying the approach for system when the IPA estimates are not unbiased (e.g., Cassandras and Lafortune 1999; Fu and Hu 1997; Glasserman 1991). This also includes the recently proposed fluid model; see ▸ Perturbation Analysis of Discrete Event Systems.

2. Another research topic is how to develop fast and efficient algorithms for estimating the performance gradients, especially in the case of Markov systems; see e.g., Cao and Wan (1998), Baxter and Bartlett (2001), and Cao (2005). This is called *policy gradients* in the reinforcement learning literature.

3. There are also research works on how the gradient estimates and policy iteration (see section "Direct Comparison and Policy Iteration") can be combined with stochastic approximation approaches to develop fast convergent optimization algorithms; see Marbach and Tsitsiklis (2001) for gradient-based approach and Fang and Cao (2004) for policy iteration-based approach.

Direct Comparison and Policy Iteration

The sensitivity-based view has been extended to optimization in discrete spaces of policies. With this view, we can develop a new approach to performance optimization based on a direct comparison of the performance of any two policies. This provides an alternative to the standard dynamic programming to solving the Markov decision processes (MDP) types of problems; it also has been applied to solve some problems when the standard MDP fails (Cao 2007; Cao and Wan 2013).

P

In an MDP, there is an action space denoted as $\mathcal{A}$. For simplicity, we only consider the discrete case. When the system is at any state $i \in \mathcal{S}$, an action $\alpha = d(i)$ is taken, which controls the system transition probability, denoted as $p^\alpha(j|i)$, $i, j \in \mathcal{S}$, and the reward function, denoted as $f(i, \alpha)$. The mapping $d : \mathcal{S} \to \mathcal{A}$ is called a *policy*. Since a policy corresponds to a transition probability matrix $P^d = [p^{d(i)}(j|i)]_{i,j=1}^M$ and the reward vector $f^d = (f(1, d(1)), \cdots, f(M, d(M)))^T$, we also call the pair (P, f) a policy.

Consider two policies (P, f) and (P', f'), and assume that the Markov chain under both policies is ergodic. We use prime " $'$ " to denote the quantities associated with (P', f'). First, multiplying both sides of the Poisson equation (6) with π' on the left and after some calculations, we get

$$\eta' - \eta = \pi'\{(P'g + f') - (Pg + f)\}. \quad (9)$$

This is called a *performance difference formula*, and many optimization results can be derived from it in an intuitive way.

Policy Iteration and the Optimality Equation

The difference formula (9) has a nice decomposition structure: it contains two factors, the first one π', which does not depend on P, and the second one $(P'g + f') - (Pg + f)$, in which all the parameters are known except the performance potential g, which can be obtained by only analyzing system with P. This nice feature makes the difference formula the basis of performance optimization.

For two M-dimensional vectors a and b, we define $a = b$ if $a(i) = b(i)$ for all $i = 1, 2 \cdots, M$; $a \leq b$ if $a(i) \leq b(i)$ for all $i = 1, 2 \cdots, M$; $a < b$ if $a(i) < b(i)$ for all $i = 1, 2 \cdots, M$; and $a \preceq b$ if $a(i) < b(i)$ for at least one i and $a(j) = b(j)$ for other components. The relation $\leq$ includes $=$, $\preceq$, and $<$. Similar definitions are used for the relations $>$, $\succeq$, and $\geq$.

Next, we note that $\pi'(i) > 0$ for all $i = 1, 2, \cdots, M$. Thus, from (9), we know that if $(P' - P)g + (f' - f) \succeq 0$, then $\eta' - \eta > 0$.

From (9) and the fact $\pi' > 0$, the proof of the following lemma is straightforward.

Lemma 1 *If $Pg + f \preceq (\leq) P'g + f'$, then $\eta < (\leq) \eta'$.*

It is interesting to note that in the lemma, we use only the potentials with one Markov chain, i.e., g. Thus, because of the special structure of the performance difference formula (9), if the condition in Lemma 1 holds, to compare the performance measures under two policies, we may only need the potentials with one policy.

Policy iteration and the optimality equation can be easily derived from (9) and Lemma 1.

Algorithm 2 Policy Iteration

1. Guess an initial policy d_0, and set $k = 0$.
2. (Policy evaluation) Obtain the potential g^{d_k} by solving the Poisson equation $(I - P^{d_k})g^{d_k} + \eta^{d_k}e = f^{d_k}$ or estimating it on a sample path. (The superscript "d_k" is added to quantities associated with policy d_k.)
3. (Policy improvement) Choose

$$d_{k+1} \in \arg\left\{\max_{d \in \mathcal{D}}\left[f^d + P^d g^{d_k}\right]\right\}, \quad (10)$$

component-wise (i.e., to determine an action for each state). If in state i, action $d_k(i)$ attains the maximum, and set $d_{k+1}(i) = d_k(i)$.
4. If $d_{k+1} = d_k$, stop; otherwise, set $k := k + 1$ and go to Step 2.

It follows directly from Lemma 1 that when the iteration does not stop, the performance improves at each iteration. It can be proved easily by construction that the iteration stops at an optimal policy. Again, from Lemma 1, when the iteration stops at a polict $\hat{d}$, it holds

$$\eta^{\hat{d}}e + g^{\hat{d}} = \max_{d \in \mathcal{D}}\left\{f^d + P^d g^{\hat{d}}\right\}. \quad (11)$$

This is the Hamilton-Jacobi-Bellman (HJB) optimality equation. If we further define the Q-factor,

$$Q^d(i, \alpha) = f(i, \alpha) + \sum_j p^\alpha(j|i)g^d(j)]. \quad (12)$$

Then the policy iteration equation (10) and the HJB equation (11) become

$$d_{k+1}(i) := \arg \max_{\alpha \in \mathcal{A}} \{Q^{d_k}(i, \alpha)\} \qquad (13)$$

and

$$Q^{\hat{d}}(i, \alpha) = \max_{\beta \in \mathcal{A}} \{Q^{\hat{d}}(i, \beta)\}. \qquad (14)$$

The only difference between (8) and (9) is that π in (8) is replaced by π' in (9). This leads to an interesting observation: *policy iteration in MDPs in fact chooses the policy with the steepest directional derivative as the policy in the next iteration.* Therefore, policy iteration in fact can be viewed as the "gradient-based" optimization in a discrete space.

In our approach, the HJB equation and policy iteration are obtained from the performance difference equation (9), which compares the performance of any two policies. It is hence called a *direct-comparison* based approach. This approach also applies to more general problems, such as multichain Markov systems, systems with absorbing states, and problems with other performance criteria such as the discounted performance and the bias, etc.

The direct-comparison approach has been successfully applied to the *n*th-bias optimality problem (Cao 2007). Essentially, starting with the performance difference formulas (those similar to (9) for different performance), we can develop a simple and direct approach to derive the results that are equivalent to the sensitive discount optimality for multichain Markov systems with long-run average criteria (Puterman 1994), and no discounting is needed and no dynamic programming is used. The approach, motivated by the development for discrete event dynamic systems, provides a clear overall picture for the area of MDP.

The direct-comparison approach can also be applied to some problems where dynamic programming fails, including the event-based optimization problems, where the sequence of events may not be Markovian; see the next section.

Event-Based Optimization

It is well known that for most systems modeled by Markov processes, the state spaces are too large, and it is not computationally feasible to implement policy iteration or to solve the HJB equations. On the other hand, in many practical problems in engineering, finance, and social sciences, control actions are only taken when certain events occur. For example, in the traffic control of a network of subnetworks, often times one cannot control the traffic in the same subnetwork, and control actions are only applied when there are packets transferring among different subnetworks. In a portfolio management problem, the investor sells or buys stocks when the price history experiences some predetermined patterns (e.g., reaches some level). In a sensor network, actions are taken only when one of the sensors detects some abnormal situations. In a material handling problem, actions are taken when the inventory level falls below certain threshold.

Conceptually, anything happened in the past can be chosen as an event. However, the number of such events is too big (much bigger than the number of states), and studying all these events makes analysis infeasible and defeats our original purpose. Therefore, to properly define events, we need to strike a balance between the generality on one hand and the applicability on the other hand.

In the event-based setting, *an event e is defined as a set of state transitions with certain common properties.* That is, $e := \{\langle i, j \rangle : i, j \in \mathcal{S}$ and $\langle i, j \rangle$ has common properties}, where $\langle i, j \rangle$ denotes a state transition from i to j. This definition can also be easily generalized to represent a finite sequence of state transitions. We shall see that in many real problems, the number of events requiring control actions is usually much smaller than that of the states.

An event-based policy d is defined as a mapping from $\mathcal{E}$ to $\mathcal{A}$, with $\mathcal{E}$ being the space of all events. That is, $d : \mathcal{E} \rightarrow \mathcal{A}$. Let $\mathcal{D}_e$ denote the set of all the stationary and deterministic policies. The reward function under policy d is denoted as $f^d = f(i, d(e))$, and the associated long-run average performance is denoted as η^d. When an event e happens, we choose an action $a = d(e)$ according to a policy d, where $e \in \mathcal{E}$ and $d \in \mathcal{D}_e$. Our goal is to find an optimal policy $\hat{d}$ which maximizes the long-run average performance as follows.

$$\hat{d} = \arg\max_{d \in \mathcal{D}_e} \{\eta^d\} \qquad (15)$$

The main difficulty in developing the event-based optimization theories and algorithms lies in the fact that the sequence of events is usually not Markovian. The standard optimization approach such as dynamic programming does not apply to such problems. However, we can apply the direct-comparison approach to this event-based optimization problem. Here we give a very brief discussion.

Consider an event-based policy d, $d \in \mathcal{D}_e$. When event e occurs, the conditional transition probability is denoted as $p^{d(e)}(j|i,e)$. Let $\pi^d(i|e)$ be the conditional steady-state probability of state i when event e occurs under policy d. Define the aggregated Q-factor

$$Q^d(e, \alpha) = \sum_i \pi^d(i|e)$$
$$\times \left[f(i, \alpha) + \sum_j p^\alpha(j|i,e)g^d(j) \right]. \quad (16)$$

We may use these aggregated Q-factors to develop an event-based policy iteration algorithms as Algorithm 2 and obtain the policy iteration equation (cf. (13))

$$d_{k+1}(e) := \arg\max_{\alpha \in \mathcal{A}} \{Q^{d_k}(e, \alpha)\}, \qquad e \in \mathcal{E}, \quad (17)$$

and the event-based HJB optimality equation (cf. (14)) is

$$Q^{\hat{d}}(e, \alpha) = \max_{\beta \in \mathcal{A}} \{Q^{\hat{d}}(e, \beta)\}. \qquad (18)$$

It can be proved that if the conditional probability $\pi^h(i|e)$ does not depend on the policy; i.e.,

$$\pi^h(i|e) = \pi^d(i|e), \quad \forall i, e, \quad \text{and } h, d, \quad (19)$$

then policy iteration (17) indeed leads to a sequence of increasing performance and (18) specifies an event-based optimal policy.

The event-based aggregated Q-factor (16) can be estimated on a sample path in the same way as for potentials (Cao 2007). The number of events requiring actions is usually much smaller than the

number of states, and in some cases such as the network admission control problem, it is linear to the system size.

The crucial condition for the above event-based optimization is (19). There are many problems, such as the control of the networks of networks and the portfolio management problem, for which the condition holds; there are also many problems for which the condition does not hold. The error in applying (18) and policy iteration (17) comes from the difference between $\pi^h(i|e)$ and $\pi^d(i|e)$ at each iteration. Further research is needed.

We use a computer network as an example, in which each computer or router can be modeled as a queueing subnetwork and the computer network is then a network of such subnetworks. Assume that there is an M subnetwork, and subnetwork m, $m = 1, 2, \cdots, M$, consists of k_m servers. The number of customers at the jth server of subnetwork m is denoted as $n_{m,j}$, $j = 1, 2, \cdots, k_m$, and the number of customers in all the servers in subnetwork m is denoted as $N_m = \sum_{j=1}^{k_m} n_{m,j}$. Suppose the service time is exponentially distributed, then the system state is $\mathbf{n} := (n_{1,1}, \cdots, n_{1,k_1}; \cdots; n_{M,1}, \cdots, n_{M,k_M})$, and the aggregated state is $\mathbf{N} := (N_1, \cdots, N_M)$. Suppose that the transition probabilities among the servers in the same subnetwork are fixed and we can only control the transition probabilities among the subnetworks, and furthermore, we can only observe $\mathbf{N}$. Then the problem can be modeled as an event-based optimization with an event being a customer transition among subnetworks, and meanwhile, the aggregated state is $\mathbf{N}$. It can be proved that the condition (19) holds, and therefore, we may apply policy iteration (17) and HJB equation (18).

Many existing problems fit the event-based framework. For example, in a partially observable Markov decision process (POMDP), we may define an observation, or a sequence of observations, as an event. Other examples include state and time aggregations, hierarchical control (hybrid systems), and options. Different events can be defined to capture the special features in these different problems. In this sense, the event-based

approach may provide a unified view to these different problems (Cao 2007).

The Sensitivity-Based Approach and Optimal Control

We refer to the approaches discussed in the previous sections the *sensitivity-based approach*. When the parameters are continuous, it is the gradient-based approach, and the focus is on developing efficient algorithms that utilize the particular system structure to estimate the gradients (to justify the algorithms, the unbiasedness or the consistency of the estimates should be proved). When the parameters are discrete, it is the direct-comparison approach that leads to policy iteration and the HJB equations, and policy iteration can be viewed as the gradient-based method in discrete spaces. This approach is different from the conventional dynamic programming, and it has been successfully applied to MDP with different criteria and the *n*-bias optimization problems as well as the event-based optimization and some other problems that dynamic programming fails.

This sensitivity-based approach was motivated by the study of discrete event dynamic systems (DEDS). It has been realized that the principles and methodologies developed for DEDSs also apply to the optimization of continuous-time and continuous-state (CTCS) systems. Here are some examples:

1. *CTCS systems:* For CTCS systems, the dynamic is driven by Brownian motions or Levy processes. The transition probability matrix in DEDS should be replaced by the infinitesimal generator in CTCS, which is an operator on the space of continuous functions. With the performance difference formulas, we can redevelop the stochastic optimal control theory for many performance measures, including the long-run average, discounted performance, and finite horizon problems, with no dynamic programming; see Cao et al. (2011).

2. *Time-inconsistent optimization problems:* In behavioral finance, people's preference is modeled with a distorted probability. For example, a risk-taking person buys lotteries, because in her/his mind, s/he enlarges the possibility of winning a large sum, and a risk averse person buys insurance, because s/he is afraid of a big loss and therefore enlarges its probability.

The optimization problem with a distorted probability suffers from the time-inconsistent issue; i.e., an optimal policy for the problem in period $[t, T]$, $0 < t < T$, is not optimal in the same period for the problem in $[0, T]$. Thus, the standard dynamic programming fails.

The gradient-based approach has been applied to the portfolio management problem with probability distortion. With this approach, we discovered that the performance with distorted probability maintains some sort of linearity called *mono-linearity*. This property shed new insights to the portfolio management problem and the nonlinear expected utility theory (Cao and Wan 2013).

Conclusion

A sensitivity-based approach has been developed to the performance optimization of discrete event dynamic systems (DEDS). The approach utilizes the dynamic structure of DEDS. For systems with continuous parameters, it is the gradient-based optimization, in which the special feature of a DEDS helps in developing efficient algorithms to estimate the performance derivatives; for systems with discrete policies, it is the direct-comparison-based approach, with which policy iteration and HJB equations can be derived intuitively by using the performance difference formulas. Policy iteration can be viewed as the gradient method in a discrete space. The estimation of gradients and the implementation of policy iteration can be carried out on a given sample path, and efficient online learning algorithms can be developed (Cao 2007).

The sensitivity-based approach was developed for DEDSs, but its principle also applies to systems with continuous-state spaces. The approach provides an alternative to the traditional dynamic programming and therefore can be applied to some problems where dynamic programming does not work.

Proportional-Integral-Derivative Control

Abstract

Since their introduction in industry a century ago, proportional–integral–derivative (PID) controllers have become the de facto standard for the process industry. In this entry, fundamentals of PID control are outlined, starting from the basic control law. Additional functionalities and the tuning and automatic tuning of the parameters are then considered.

Keywords

Anti-windup; Autotuning; Controller tuning; Derivative action; PI control; Proportional control; Proportional-integral-derivative control; Ziegler-Nichols

Introduction

A proportional–integral–derivative (PID) controller is a three-term controller that has a long history in the automatic control field, starting from the beginning of the last century. Owing to its intuitiveness and relative simplicity, in addition to the satisfactory performance that it is

able to provide with a wide range of processes, it has become the de facto standard controller in industry. It has been evolving along with the progress of technology, and nowadays it is very often implemented in digital form rather than with pneumatic or electrical components. It can be found in virtually all kinds of control equipments, either as a stand-alone (single-station) controller or as a functional block in Programmable Logic Controllers (PLCs) and Distributed Control Systems (DCSs). Actually, the new potentialities offered by the development of the digital technology and of the software packages have led to a significant growth of the research in the PID control field: new effective tools have been devised for the improvement of the analysis and design methods of the basic algorithm as well as for the improvement of the additional functionalities that are implemented with the basic algorithm in order to increase its performance and its ease of use.

The success of the PID controllers is also enhanced by the fact that they often represent the fundamental component for more sophisticated control schemes that can be implemented when the basic control law is not sufficient to achieve the required performance or when a more complicated control task is of concern.

Basics

Using a PID controller means applying a feedback controller that consists of the sum of three types of control actions: a proportional action, an integral action, and a derivative action.

The proportional control action is proportional to the current control error, according to the expression

$$u(t) = K_p e(t) = K_p(r(t) - y(t)), \quad (1)$$

where u is the controller output, K_p is the proportional gain, r is the reference signal, and y is the process output. Its meaning is straightforward, since it implements the typical operation of increasing the control variable when the control error is large (with appropriate sign). The transfer

function of a proportional controller can be trivially derived as

$$C(s) = K_p. \quad (2)$$

The main drawback of using a pure proportional controller is that, in general, it cannot set to zero the steady-state error. This motivates the addition of a bias (or reset) term u_b, namely,

$$u(t) = K_p e(t) + u_b. \quad (3)$$

The value of u_b can then be adjusted manually until the steady-state error is reduced to zero.

In commercial products, the proportional gain is often replaced by the proportional band PB, which is the range of error that causes a full-range change of the control variable, i.e.,

$$PB = \frac{100}{K_p}. \quad (4)$$

The integral action is proportional to the integral of the control error, i.e.,

$$u(t) = K_i \int_0^t e(\tau) d\tau, \quad (5)$$

where K_i is the integral gain. It appears that the integral action is related to the past values of the control error. The corresponding transfer function is

$$C(s) = \frac{K_i}{s}. \quad (6)$$

The presence of an integral action allows to reduce the steady-state error to zero when a step reference signal is applied or a step load disturbance occurs. In other words, the integral action is able to set automatically the correct value of u_b in (3) so that the steady-state error is zero. For this reason, the integral action is also often called *automatic reset*.

While the proportional action is based on the current value of the control error and the integral action is based on the past values of the control error, the derivative action is based on the predicted future values of the control error. An ideal derivative control law can be expressed as

P

$$u(t) = K_d \frac{de(t)}{dt}, \qquad (7)$$

where K_d is the derivative gain. The corresponding controller transfer function is

$$C(s) = K_d s. \qquad (8)$$

The meaning of the derivative action can be better understood by considering the first two terms of the Taylor series expansion of the control error at time T_d ahead:

$$e(t + T_d) \simeq e(t) + T_d \frac{de(t)}{dt}. \qquad (9)$$

If a control law proportional to this expression is considered, i.e.,

$$u(t) = K_p \left(e(t) + T_d \frac{de(t)}{dt} \right), \qquad (10)$$

this naturally results in a PD controller. The control variable at time t is therefore based on the predicted value of the control error at time $t + T_d$. For this reason, the derivative action is also called *anticipatory control*, or *rate action*, or *pre-act*.

The combination of the proportional, integral, and derivative actions can be done in different ways. In the so-called *ideal* or *non-interacting* form, the PID controller is described by the following transfer function:

$$C_i(s) = K_p \left(1 + \frac{1}{T_i s} + T_d s \right), \qquad (11)$$

where K_p is the proportional gain, T_i is the integral time constant, and T_d is the derivative time constant. An alternative representation is the *series* or *interacting form*:

$$C_s(s) = K_p' \left(1 + \frac{1}{T_i' s} \right) \left(T_d' s + 1 \right)$$

$$= K_p' \left(\frac{T_i' s + 1}{T_i' s} \right) \left(T_d' s + 1 \right), \quad (12)$$

where the fact that a modification of the value of the derivative time constant T_d' affects also the proportional action justifies the nomenclature

adopted. Suitable conversion formulae can be applied to obtain an ideal PID controller equivalent to a series one. Obtaining an equivalent PID controller in series form starting from an ideal one is possible only if the zeros of the ideal PID controller are real.

Additional Functionalities

The expression (11) or (12) of a PID controller is actually not employed in practical cases because of a few problems that can be solved with suitable modifications of the basic control law.

Modifications of the Derivative Action
From Expressions (11) and (12), it appears that the controller transfer function is not proper, because of the derivative action, and therefore, it cannot be implemented in practice. Indeed, the high-frequency gain of the pure derivative action is responsible for the amplification of the measurement noise in the manipulated variable. This problem can be solved by filtering the derivative action with (at least) a first-order low-pass filter. The filter time constant should be selected in order to suitably filter the noise and to avoid a significant influence on the dominant dynamics of the PID controller. Thus, it can be selected as T_d/N, where N generally assumes a value between 1 and 33, although in the majority of the practical cases its setting falls between 8 and 16. Alternatively, the overall control variable can be filtered.

Another issue related to the derivative action that has to be considered is the so-called derivative kick. In fact, when an abrupt (stepwise) change of the set-point signal occurs, the derivative action is very large, and this results in a spike in the control variable signal, which is undesirable. This problem could be simply avoided by applying the derivative term to the process output only instead of the control error. In this case, the ideal (not filtered) derivative action becomes

$$u(t) = -K_p T_d \frac{dy(t)}{dt}. \qquad (13)$$

Obviously, when the set-point signal is constant, applying the derivative term to the control error or to the process variable is equivalent. Thus, the load disturbance rejection performance is the same in both cases.

Set-Point Weighting for Proportional Action

A typical problem with the design of a feedback controller is to achieve a high performance both in the set-point following task and in the load disturbance rejection task at the same time. For example, for stable processes, a fast load disturbance rejection is achieved with a high-gain (aggressive) controller, which gives an oscillatory set-point step response on the other side. This problem can be approached by using a two-degree-of-freedom control architecture, where a feedback controller is designed to achieve a high bandwidth and therefore a satisfactory load disturbance rejection performance, and then the set-point signal is filtered before applying it to the closed-loop system.

In the context of PID control, this can be achieved by weighting the set-point signal for the proportional action, that is, to define the proportional action as follows:

$$u(t) = K_p(\beta r(t) - y(t)), \qquad (14)$$

where the value of β is between 0 and 1.

In this way, the control scheme has a feedback controller (11), and the set-point signal is filtered by the system

$$F(s) = \frac{1 + \beta T_i s + T_i T_d s^2}{1 + T_i s + T_i T_d s^2}. \qquad (15)$$

The load disturbance rejection task is decoupled from the set-point following task, and obviously it does not depend on the weight β, which can be employed to smooth the (step) set-point signal in order to damp the response to a set-point change. The smaller the value of β, the smaller the overshoot and the higher the rise time.

Anti-windup

One of the most well-known possible sources of performance degradation is the so-called integrator windup phenomenon, which occurs when the controller output saturates (typically when a large set-point change occurs). In this case, the system operates as in the open-loop case, since the actuator is at its maximum (or minimum) limit, regardless of the process output value. The control error decreases more slowly than in the ideal case (where there are no saturation limits), and therefore, the integral term becomes large (it *winds up*). Thus, even when the value of the process variable attains that of the reference signal, the controller still saturates due to the integral term, and this generally yields large overshoots and settling times.

In order to cope with this problem, an additional functionality designed for this purpose can be conveniently used. This can be done in different ways. For example, in the conditional integration approach, the integration is stopped when the control variable saturates and the control error and the control variable have the same sign. Alternatively, in the back-calculation approach, the integral term is recomputed when the controller saturates by feeding back the difference of the saturated and unsaturated control signal.

Tuning

The selection of the PID parameters, i.e., the tuning of the PID controller, is obviously the crucial issue in the overall controller design. This operation should be performed in accordance with the control specifications (which should take into account the set-point following, the load disturbance rejection, the control effort, and the robustness of the system). A major advantage of the PID controller is that its parameters have a clear physical meaning, and therefore, manual tuning is relatively simple. For example, for stable processes, increasing the proportional gain leads, in general, to a faster but more oscillatory response. In fact, by increasing K_p for the same value of the control error, the proportional control action increases, and so does the aggressiveness

of the controller. Then, increasing the integral time constant (i.e., decreasing the effect of the integral action) results, in general, in a slower response but in a more damped system. This is because a larger value of T_i implies a smaller value of the control action at a given time instant of the transient response (assuming the same values of the past control errors). Finally, increasing the derivative time constant gives a damping effect. Indeed, if the set point is constant, the derivative action is proportional to the derivative of the process variable with a negative sign, and therefore, the derivative action increases (with a negative sign) when the slope of the transient response increases (so that a big overshoot is avoided). However, in this context, much care should be taken to avoid increasing the derivative time constant too much as an opposite effect might occur in this case and an unstable system could eventually result. This is because the prediction over a too long time interval might be wrong.

The above considerations can be understood by considering a transient response in the time domain but also by considering the frequency response of the system and how it changes by modifying the PID parameters. For example, the effect of increasing the three controller actions can be seen as translating any point of the Nyquist plot in each of the directions shown in Fig. 1.

From another point of view, analogous considerations can be done by considering the Bode plot. For example, considering a PID controller in ideal form with a filter on the overall control action, the effect of modifying the three parameters in the controller Bode plot is shown in Fig. 2. The effects of the parameter modification in the achieved performance can be better ascertained by plotting the frequency response of the loop transfer function for different cases. As an example, consider the process $P(s) = 1/(10s + 1)e^{-4s}$ and the PID controller $C(s) = K_p(1 + \frac{1}{T_i s} + T_d s)\frac{1}{T_f s + 1}$ where the parameters are in the following ranges: $K_p \in [2, 15/4]$, $T_i \in [4, 16]$, $T_d \in [1.5, 4]$, being always $T_f = 0.1$. From Fig. 3, it appears that an increment of K_p yields an increment of the bandwidth and a decrement of the phase margin. Conversely, an increment of T_i has an opposite effect. Finally, it can be seen that the increment of T_d initially yields to an increment of the bandwidth and of the phase margin at the same time, but then a sudden increment of the bandwidth occurs, and this corresponds to a sudden decrement of the phase margin (because of the dead time of the process) with a possible loss of stability.

In any case, in order to ease the procedure, a large number of tuning rules have been proposed in the last century, starting from the well-known Ziegler–Nichols ones (Nichols and Ziegler 1942).

PID Control, Fig. 1 Effect of an increment of the three PID control actions on a point of the Nyquist plot
Different approaches in this context are analyzed hereafter.

Empirical Tuning

Empirical tuning methods (like the Ziegler–Nichols and its refinements, Cohen–Coon, or Chien–Hrones–Reswick ones (O'Dwyer 2006)) consist in selecting the parameters of the PID controllers by using some empirical formulae which give the PID gains based on parameters of the process. Usually, the process parameters are those of a first-order-plus-dead-time (FOPDT) model or the ultimate gain and frequency of the process itself (the ultimate gain is the largest value of a proportional-only control that produces a sustained oscillation of the process variable, that is, that results in a marginally stable closed-loop system, while the ultimate frequency is the frequency of the corresponding sustained oscillation). These parameters can be obtained by means of a simple open-loop (step response) or closed-loop (relay feedback) experiment.

Model-Based Tuning

In model-based tuning (like the Dahlin's and Haalman's methods and the Internal Model Control one (O'Dwyer 2006)), the PID control law is determined analytically starting from a process model and by selecting an appropriate (closed-loop) target transfer function. The user generally selects the desired closed-loop time constant as a tuning parameter which allows the handling of the trade-off between aggressiveness and robustness (and control effort). In this context, according to the well-known SIMC (Simplified Internal Model Control) tuning rules (Skogestad 2003), the closed-loop time constant should be selected equal to the dead time of the process.

Optimal Tuning

Optimal tuning rules aim at minimizing a given objective function. Usually, an integral function of the control error is selected for this purpose, for example,

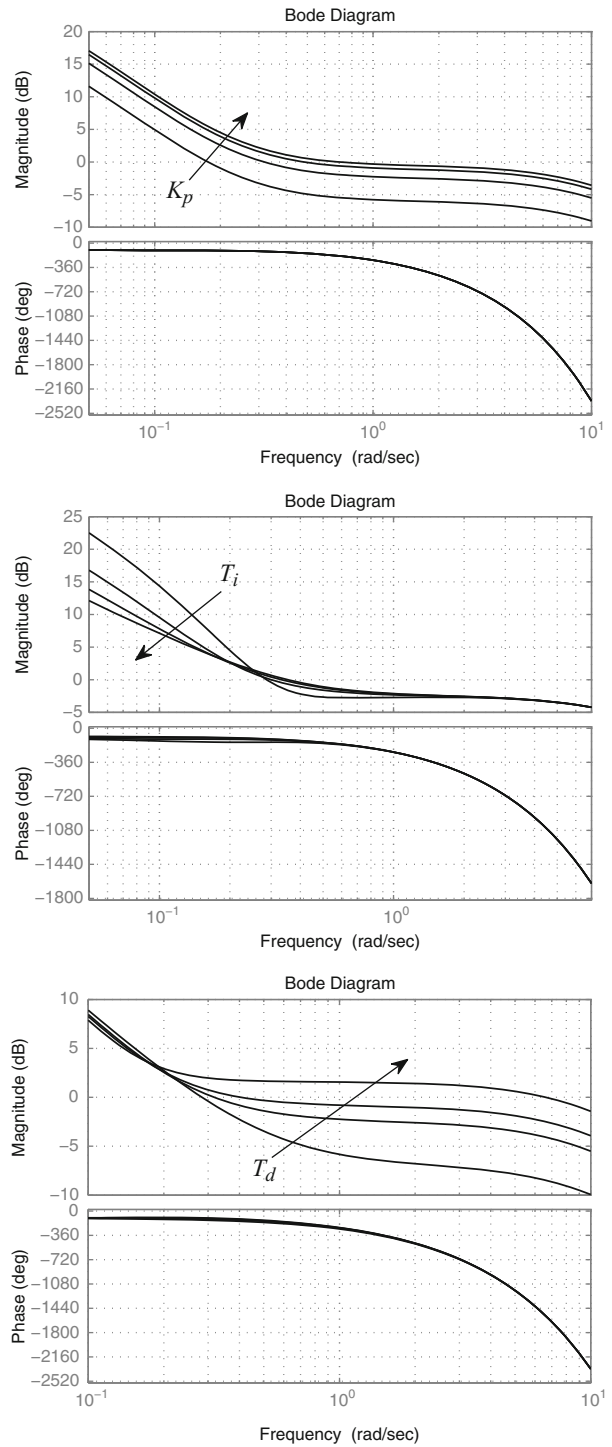
$$J = \int_0^\infty t^n e^2(t) dt \qquad (16)$$

where $n = 0, 1, 2$ or the Integrated Absolute Error

$$IAE = \int_0^\infty |e(t)| dt. \qquad (17)$$

By solving the optimization problem for different kinds of (normalized) processes and by interpolating the results, it has been possible to obtain tuning formulae that give the PID gains based on the process parameters. Actually, it should be noted that as no (robustness) constraints are considered in the optimization procedure, a poor robustness may eventually result in the control system.

Robust Tuning

Recently, tuning rules which explicitly consider the robustness issue have been devised. In particular, the maximum of the sensitivity function is often considered as robustness index. A selected value of M_s is then employed as a constraint in finding the optimal PID parameters which minimize a given performance index. An additional constraint on the maximum complementary sensitivity function can also be considered. For example, the AMIGO tuning rules (Åström and Hägglund 2004) have been devised by applying this approach, where the integral gain is maximized in order to obtain the best reduction of load disturbances.


Automatic Tuning

The functionality of automatically identifying the process model and tuning the controller based on that model is called automatic tuning (or, simply, auto-tuning) (▶ Autotuning). In particular, an identification experiment is performed after an explicit request of the operator, and the values of the PID parameters are updated at the end of it (for this reason, the overall procedure is also called *one-shot automatic tuning* or *tuning-on-demand*). The design of an automatic tuning procedure involves many critical issues, such as the choice of the identification procedure (usually based on an open-loop step response or on a relay feedback experiment), of the a priori selected

(parametric or non parametric) process model, and of the tuning rule.

The one-shot automatic tuning functionality is available in practically all the single-station controllers available on the market. More advanced control units might provide a *self-tuning* functionality, where the identification procedure is continuously performed during routine process operation in order to track possible changes of the system dynamics and the PID parameters values are adaptively modified. In this case, all the issues related to adaptive control have to be taken into account. In particular, performance assessment methodologies, which are capable to evaluate if the PID design can be improved, are of significant relevance in this context (▶ Controller Performance Monitoring).

Design Tools

Although one of the major advantages of PID controllers is their relative simplicity, Computer-Aided Control System Design tools (▶ Computer-Aided Control Systems Design: Introduction and Historical Overview) have been developed in order to help the user in their design (starting from the identification of the process) by taking into account the different control requirements in a given application (Guzman et al. 2008). In this context, all the additional functionalities can be considered, as well as more complex control architectures where, in any case, the PID control is still the basic element (▶ Control Structure Selection, ▶ Control Hierarchy of Large Processing Plants: An Overview).

Summary and Future Directions

PID controllers are the most employed controllers in industry, and the knowledge about their use is well established, with the presence of many effective tuning and automatic tuning techniques. Despite this, PID controllers are still being developed under many points of view. For example, design methodologies for more complex control schemes (like cascade control or control of multivariable systems with or without the use of a decoupling strategy) can be improved. Further, the advancement of the technologies poses new problems that need to be addressed. For example, the use of wireless sensors and actuators calls for event-based PID controllers whose design should take into account the asynchronous sampling. The availability of faster and faster microprocessors has also stimulated an increasing interest in fractional-order PID controllers which allows a more flexible design at the expense of an increment of the complexity.

Recommended Reading

Basic concepts of PID controllers can be found in almost every book on process control. For a detailed treatment, see (Åström and Hägglund 2006) where all the methodological as well as technological aspects are covered. An excellent collection of tuning rules can be found in O'Dwyer (2006). More advanced topics can be found in Tan et al. (1999), Yu (2006), Johnson and Moradi (2005), Knospe (2006), Visioli (2006), Wang et al. (2008), Visioli and Zhong (2010), and Vilanova and Visioli (2012).

Pilot-Vehicle System Modeling

Alexander Efremov
Moscow Aviation Institute, Moscow, Russia

Abstract

The main types and variables of pilot-aircraft systems and pilot control response characteristics are considered. The basic regularities of pilot behavior exposed in closed-loop systems are briefly discussed. Different types of models of pilot behavior are reviewed including classical models (McRuer's and structural) and an optimal control model.

Keywords

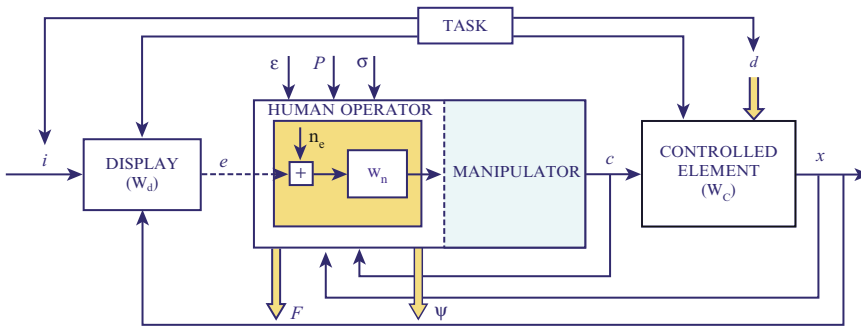
Crossover pilot model; Describing function; Manual control; Pilot behavior; Pilot optimal control model Remnant spectral density; Structural model

Introduction

Modern flight control and navigation systems are characterized by two features: (1) they employ fly-by-wire controls and (2) they introduce extensive automation support into the cockpit, ranging from complex augmented flight control systems in manual control modes to powerful flight management computers and autopilots that assume responsibility for most flight control tasks (and which may operate the aircraft in ways that are difficult for pilots to monitor and understand). These modern systems leave the pilot in a supervisory control mode most of the time. Consequently, crew members monitor, supervise, plan, and, in essence, serve as information managers. The level of supervisory control tasks can be different from conventional command control in which the operator issues auto-pilot commands ("set altitude", "set airspeed," etc.) and task-level control in which the operator issues commands such as "line formation," "trail formation," etc. Although civilian pilots have experience flying their aircraft manually, they are seldom in active, direct control of the aircraft. However, if a failure or unexpected upset occurs, they are required to assume control immediately. As for military pilots, they (especially fighter pilots) use manual control in the majority of piloting tasks.

The effective use of manned flight vehicles has always required a satisfactory match of vehicle characteristics (which include vehicle dynamics, control manipulators, displays) with the human pilot's characteristics as a flight controller. The provision of proper vehicle handling qualities by the flight control system and display and manipulator design has often posed serious problems which the vehicle system engineer must solve.

Their solutions require the knowledge of mutual interactions between the pilot and the vehicle. The understanding of such interactions requires a mathematical theory which can be used to explain known findings and to predict new ones. For handling qualities, such theory is based on the methods of control engineering and treats the pilot-vehicle system as a closed-loop (in general, a multiloop) entity. The sine qua non of the theory is a model of pilot dynamic characteristics

P


Pilot-Vehicle System Modeling, Fig. 1 Pilot-aircraft system

in a form suitable for application using relatively conventional control engineering techniques. An adequate description of a pilot's dynamics response characteristics is not easily obtained because of the pilot's inherent adaptability and capacity for learning.

Main Variables of the Pilot-Aircraft System

The pilot-aircraft manual control system, shown in Fig. 1, is characterized by a number of variables. The main group of these variables is the so-called task variables which comprise all the system inputs (command inputs $i(t)$, disturbances $d(t)$) and control system elements (display, manipulators, and controlled element dynamics, which is defined by the aircraft frame and flight control system dynamics).

A specific feature of pilot-aircraft systems is the dependence of the piloting task on the task variables. For different piloting tasks, these variables or their parameters differ too. Stability of the closed-loop system is always a necessary, though not sufficient, criterion for the control strategy. Consequently, the pilot's dynamics are profoundly affected by the display and controlled element dynamics, because his response must be adapted to provide the necessary loop stability and accuracy. The characteristics of the other task variables $(i(t), d(t))$, related to the mission and control strategy, also exert direct influence on the pilot dynamics, although their effects are more

in the nature of adjustment and emphasis than of changes in fundamental form.

These variables constitute an enormous range of possible conditions and piloting tasks. In addition to the task variables, the other groups of variables–procedural (p–instructions, training schedule order of presentation of trials etc.), environmental (ε–illumination, vibration, temperature, and so forth), pilot centered (σ–physical condition, motivation etc.)—have less influence on pilot-aircraft system features.

Types of Pilot-Aircraft Systems

The structure of the pilot-aircraft system depends on the piloting task. Some tasks (for example, the pitch tracking task) can be interpreted with the help of the single loop compensatory block diagram. In that case the pilot perceives only the error signal, $y(t) = e(t) = i(t) - x(t)$, and control $c(t)$. Figure 1 is the pilot pitch control command. The other tasks require more complicated descriptions. For example, the landing task is a multiloop compensatory task, where the inner loop closed by the pilot is the pitch control loop. Some piloting tasks are multichannel control tasks, in which the pilot perceives several visual stimuli (for example pitch angle and bank angle) and generates commands in several channels too. Pilots also perceive stimuli of different sensing modalities (visual, vestibular, kinesthetic). In cases where these influence his actions, the multimodality of the pilot-aircraft system has to be analyzed.

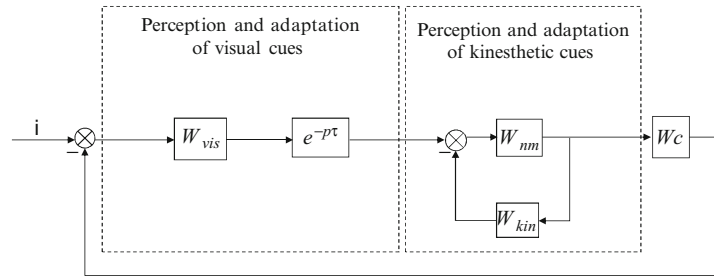
A great many past experiments in which human dynamic measurements were taken have been conducted for investigation of compensatory tracking tasks. Some practical piloting tasks (e.g., aim-to-aim tracking in case when the target flies against a background of clouds) correspond to pursuit conditions. In that case, the pilot perceives the information about the error signal $e(t)$ and the input signal $i(t)$.

In many piloting tasks the single loop compensation system defines the main features of more complicated types of pilot-aircraft systems and its flying qualities. Therefore, this type of the system has been investigated in more depth.

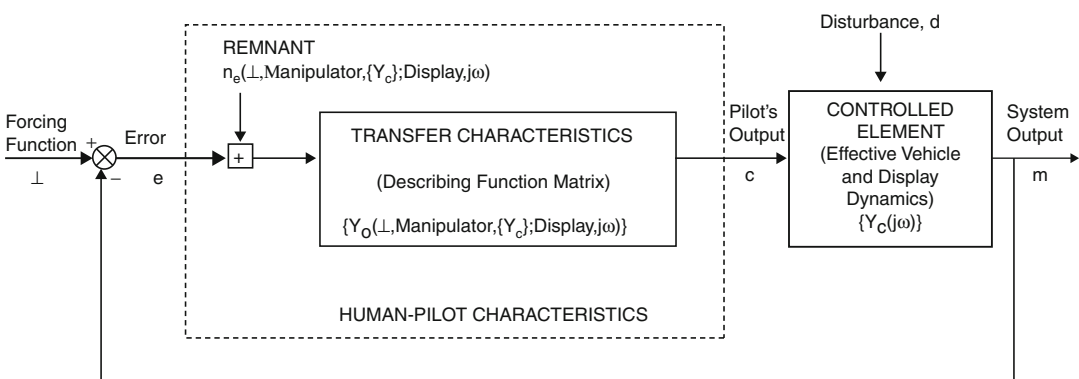
Pilot Control Response Characteristics

The most obvious aspect of human dynamic behavior in a manual control task is the pilot's control actions within that task. When the key variables are fixed and the signals in the control loop are approximately time stationary over an interval of interest, the pilot-vehicle system can be presented as a quasi-linear system. In that case, the pilot response can be presented by two components: the pilot-describing function, $W_p(j\omega)$, taking into account the linear portion of pilot response on the stimulus $e(t)$, and remnant $n_e(t)$, which takes into account all nonlinear, nonstationary effects of pilot behavior (Fig. 2).

In the majority of piloting tasks $n_e(t)$ is a stationary process characterizing the remnant spectral density $S_{n_e n_e}(\omega)$ (McRuer and Krendel 1974). The pilot control response characteristics $W_p(j\omega)$ and $S_{n_e n_e}(\omega)$ depend explicitly on the task variables (McRuer and Jex 1967; McRuer et al. 1968). In much experimental research, the technique for identification of these characteristics was based on the use of an input signal consisting of the sum of non-harmonically-related sine waves with cut off frequency ω_i at 1.5, 2.5, and 4 rad/s and different controlled element dynamics (Allen and Jex 1972; Magdaleno 1972; Shirley 1969).

In addition to control response, other types of pilot's responses also characterize his behavior: physiological (F) and psychophysiological ψ responses (Fig. 1). For one of the psychophysiological response characteristics, the pilot opinion rating (PR) is widely used in experimental investigations as well as for the measurement of pilot control response. Pilot opinion ratings are defined by specialized scales (e.g., the Cooper-Harper scale (Cooper and Harper 1969)).


Modeling Pilot Behavior in Manual Control

Experimental investigations have demonstrated a specific regularity: for a variety of forcing functions and controlled elements the slope of the


Pilot-Vehicle System Modeling, Fig. 2 Quasi-linear paradigm for the human pilot

Pilot-Vehicle System Modeling, Fig. 3 Pilot structural model

open-loop describing function $|W_{OL}(j\omega)|$ vs frequency was *unity, i.e., −20 dB/dec* in the region of the crossover frequency ω_c (McRuer and Jex 1967). This observation has led to the conclusion that near ω_c, $W_{OL}(j\omega)$ can be presented by the "crossover model" (McRuer and Jex 1967)

$$W_{OL}(j\omega) = W_p(j\omega) \cdot W_C = \frac{\omega_c}{j\omega} e^{-j\omega\tau_e}$$

This model has two parameters:

$$\omega_c = \omega_{co}(\omega_c) + \Delta\omega(\omega_i)$$
$$\tau_e = \tau_o(\omega_c) + \Delta\tau(\omega_i)$$

For the controlled element dynamics $W_C = \frac{K}{s(Ts+1)}$, the increase of constant T leads to an increase of τ_0 and a decrease of ω_{C0}. The empirical dependences of $\Delta\omega_c$ and $\Delta\tau_e$ on ω_i obtained for the rectangular form of input spectrum are the following: $\Delta\omega = 0.18\omega_i$, $\Delta\tau = -0.07\omega_i$.

McRuer proposed several modifications of the open-loop system crossover and pilot describing function models (McRuer and Krendel 1974). One of the simplest ones (used widely in many researches) which might be recommended for description of pilot-aircraft system characteristics in the crossover frequency range is the following

$$W_p(j\omega) = K_p \frac{T_L j\omega + 1}{T_1 j\omega + 1} e^{-j\omega\tau_e}$$

The selection of the parameters K_p, T_L, and T_I is carried out by using "adjustment rules" so that the closed-loop system conforms to experimental frequency response characteristics. These adjustment rules reflect the main features of pilot behavior – adaptation and optimization.

A more complicated model of pilot describing function ("structural model") was offered by R. Hess (1979, 1984). It takes into account the additional inner loop generated by the pilot as a result of his response to the kinesthetic cue (Fig. 3). The modification of this model (Efremov and Tjaglik 2011) demonstrated good agreement with the pilot describing function as measured in experiments. One of the features of this modified model is the criterion used for the parameter optimization: $I = \min[\sigma_e^2]$ or $I = \min[\sigma_e^2 + \beta\sigma_n^2]$. This procedure requires the knowledge of the pilot remnant spectral density. For the single loop system, such a model was developed by Levison et al. (1969).

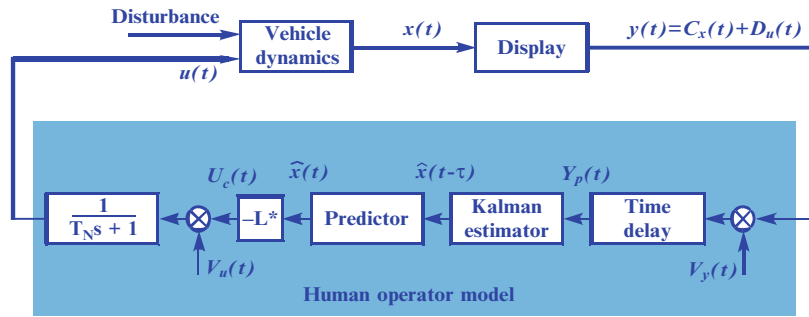
$$S_{n_e n_e}(\omega) = 0.01\pi \frac{\sigma_e^2 + \sigma_e^2 T_L^2}{1 + T_L^2 \omega^2}$$

In the limited number of researches, the classic approach to pilot modeling considered above was used for more complicated types of the pilot-aircraft system, when the pilot perception of motion cues was taken into account (multimodality system (Hess 1990)) or for a case of the multiloop pilot-aircraft system (Stapleford et al. 1967).

A different approach to pilot behavior modeling was developed by Kleiman et al. (1970). It is based on the modern optimal control theory and assumes that the pilot's goal is to minimize the cost function:

$$I = \lim_T \frac{1}{T} \int_0^T (xQx^T + uQ_c u^T + \dot{u}G_c\dot{u}^T)dt$$

The model takes into account the main pilot limitation parameters: time delay in perception,

Pilot-Vehicle System Modeling, Fig. 4 Optimal pilot model


the observation and motor noises, and the neuro-muscular dynamics.

The predictive part of the model consists of the optimal controller ($-L^*$), Kalman filter and predictor (Fig. 4). The software for definition of these elements allows the use of this model for the different types of the pilot-aircraft systems.

The classical and optimal pilot behavior models have been applied widely for different manual control tasks: the development of alternative criteria for flying qualities (Efremov et al. 1998; Neal and Smith 1971), the flight control system (Schmidt 1979) and display design (Klein and Clement 1973), the analysis of reasons for pilot-induced oscillation (McRuer 1997) and the development of means for its suppression (Efremov 1995), and many others.

In some of the researches, attempts have been made to find the relationship between the parameters of the closed-loop system, pilot control response characteristics, and pilot opinion ratings. The technique developed in these researches is called the "paper pilot technique" (Anderson 1970). The following modification of this technique has enabled a close match between the results of mathematical modeling (PR, T_L, accuracy, etc.) of the different types of the pilot-aircraft system and the results of experimental investigations (Efremov and Ogloblin 2006).

Summary and Future Directions

Pilot behavior has been studied extensively for single-loop stationary manual control tasks. Two approaches to the mathematical modeling of the pilot behavior have been developed: classical and optimal control. Both of them have produced good agreement with experimental results. The discussed models describe one of the main features of the pilot adaptation – "parameter adaptation", when a change of any task variable causes a change of human operator control response characteristics. Only a limited number of experimental investigations have been carried out for more complicated cases: multiloop and multimodality pilot-aircraft closed-loop systems. Broader investigations are necessary in the future to obtain accurate pilot mathematical models for these cases. Future investigation in pilot behavior modeling area is also necessary for better formulations of other aspects of pilot adaptation:

– "Structural adaptation", when the pilot selects the loops and the best type of behavior (compensatory, pursuit, etc.) appropriate for the different task variables and, in the case of the flight control system, changes in dynamics.

– "Goal adaptation", when a change of the piloting task or a failure in the controlled element dynamics is accompanied by a change of the goals.

Other future directions in pilot modeling are the development of models to predict the results in the case of sharp changes of controlled element dynamics, to optimize the controlled element dynamics, to define the relationship between the pilot control response characteristics and his opinion rating in different piloting tasks, to get new criteria for the handling qualities, prediction of pilot-induced oscillations, and to solve many other manual control problems.

Polynomial/Algebraic Design Methods

Vladimír Kučera
Faculty of Electrical Engineering, Czech Technical University of Prague, Prague, Czech Republic

Abstract

Polynomial techniques have made important contributions to systems and control theory. Algebraic formalism offers several useful tools for control system design. In most cases, control systems are designed to be stable and to meet additional performance specifications, such as optimality or robustness. The basic tool is a

parameterization of all controllers that stabilize a given plant. Optimal or robust controllers are then obtained by an appropriate selection of the parameter. An alternative tool is a reduction of controller synthesis to a solution of a polynomial equation of specific type. These two polynomial/algebraic approaches will be presented as closely related rather than isolated alternatives.

Keywords

Controller synthesis; Linear systems; Polynomial equation approach to control system design; Youla-Kučera parameterization of stabilizing controllers

Stabilizing Controllers

The majority of control problems can be formulated using the diagram shown in Fig. 1. Given a plant S, determine a controller R such that the feedback control system is stable and satisfies some additional performance specifications, such as reference tracking, disturbance attenuation, optimality, or robustness.

Suppose that the plant and the controller are linear time-invariant single-input single-output continuous-time systems with real *rational* transfer functions S and R, respectively. Stability is understood as the *input-output stability*, i.e., whenever the exogenous inputs δ and ρ are essentially bounded in amplitude, so too are the output signals μ and η (hence also ε and ν).

It is natural to separate the design task into two consecutive steps: (1) stabilization and (2) achievement of additional performance specifications. To do this, all solutions of the first step, i.e., *all controllers that stabilize the given plant*, must be found.

How can one characterize such controllers? Denote H_s the reference-to-error transfer function (sometimes called the sensitivity function) and H_c the disturbance-to-control transfer function (the so-called complementary sensitivity function) in the closed-loop control system, namely,

$$H_s = \frac{1}{1 + SR}, \quad H_c = \frac{SR}{1 + SR}.$$

Now suppose that S can be expressed as the ratio of two coprime polynomials, $S = b/a$, and that the controller has alike form, $R = q/p$. Then the two closed-loop transfer functions can be written as

$$H_s = a \, \frac{p}{ap + bq} := aX,$$

$$H_c = b \, \frac{q}{ap + bq} := bY$$

Consequently, if R stabilizes S, then the rational functions X and Y are bound to be stable. These functions cannot be arbitrary, however, since $H_s + H_c = 1$. The stability equation follows as

$$aX + bY = 1.$$

Any stabilizing controller for S can be expressed as $R = Y/X(= q/p)$, where X and Y are a stable rational solution pair of the stability equation. This solution can be expressed in parametric form:

$$X = x + bW, \quad Y = y - aW,$$

furnishing in turn an explicit parameterization of the set of all stabilizing controllers for S:

$$R = \frac{y - aW}{x + bW},$$

known as the *Youla-Kučera parameterization*. Here x and y are any polynomials satisfying the Bézout equation $ax + by = 1$, while W is a free parameter ranging over the set of stable real rational functions such that $x + bW$ is not identically zero.
Polynomial/Algebraic Design Methods, Fig. 1 Feedback control system

Example 1 Consider an integrator plant $S(s) = 1/s$. The Bézout equation admits a solution $x = 0$, $y = 1$ so that the set of all stabilizing controllers for S is given by

$$R(s) = \frac{1 - sW}{W}$$

for any stable real rational $W \neq 0$.

The parameter

$$W(s) = \frac{1}{s + 1}$$

yields $R = 1$, a proportional gain controller. The parameter

$$W(s) = \frac{s}{s^2 + s + 1}$$

results in a proportional-integral controller

$$R(s) = 1 + \frac{1}{s}.$$

Taking $W = 1$ leads to the stabilizing controller $R(s) = 1 - s$. The feedback system is stable, but it has a pole at $s = \infty$.

Additional Performance Specifications

There is a simple formula that generates all the stabilizing controllers for a given plant. Using this formula, we can obtain a parameterization of all stable closed-loop transfer functions that can be obtained by stabilizing a given plant. The bonus is that the parameterization is *affine* in the free parameter W. In contrast, the controller R appears in a nonlinear fashion:

$$\begin{bmatrix} v \\ y \end{bmatrix} = \frac{1}{1 + SR} \begin{bmatrix} 1 & R \\ S & SR \end{bmatrix} \begin{bmatrix} d \\ r \end{bmatrix}$$

$$= \begin{bmatrix} a(x + bW) & a(y - aW) \\ b(x + bW) & b(y - aW) \end{bmatrix} \begin{bmatrix} d \\ r \end{bmatrix}.$$

As R and W are in a one-to-one correspondence, it is convenient to use W in lieu of R in the

design process and calculate R subsequently. Thus, the parameterization of all stabilizing controllers makes it possible to separate the design process into two steps: the determination of all stabilizing controllers and the selection of the parameter that achieves the remaining design specifications. The extra benefit is that both tasks are linear.

Asymptotic Properties

Asymptotic properties of control systems can easily be accommodated in the sequential design procedure. These include the elimination of an offset due to step references, the ability of system output to follow a class of reference signals, or the asymptotic elimination of specific disturbances.

In Fig. 1, asymptotic *reference tracking* means that the output η follows the reference ρ as time approaches infinity, which is to say that the error ε approaches zero for large times. On the other hand, we speak of asymptotic *disturbance elimination* if the effect of the disturbance δ decreases at the output η for increasing time. In terms of Laplace transforms, $\varepsilon = H_s\rho$ and $\eta = SH_s\delta$ are to be *stable* rational functions.

Example 8.1 Consider the plant $S(s) = 1/(s + 1)$. The Bézout equation admits a solution $x = 0$, $y = 1$. The set of all stabilizing controllers for S is

$$R(s) = \frac{1 - (s + 1)W}{W}$$

for any stable real rational $W \neq 0$. The achievable sensitivity transfer functions are $H_s = (s + 1)W$.

To track a step reference, $\rho = 1/s$, we must take $W = sW_1$ for any stable rational $W_1 \neq 0$. To eliminate a sinusoidal disturbance, $\delta = s/(s^2 + \omega^2)$, we constrain the parameter as $W = (s^2 + \omega^2)W_2$ for any stable rational $W_2 \neq 0$. To meet both requirements, we simply take $W = s(s^2 + \omega^2)W_3$ for any stable rational $W_3 \neq 0$, say $W = s(s^2 + \omega^2)/(s + 1)^4$.

The resulting controller is

$$R(s) = \frac{3s^3 + (6 - \omega^2)s^2 + (4 - \omega^2)s + 1}{s(s^2 + \omega^2)}.$$

The controller obtained in Example 8.1 demonstrates the internal model principle: the unstable modes to be followed or eliminated must be generated by the controller unless they are present in the plant.

H$_2$ Optimal Control

The sequential design procedure will be further illustrated on the design of *linear-quadratic optimal* controllers. Given a plant with transfer function $S = b/a$, the task is to find a controller that stabilizes the control system of Fig. 1 while minimizing the H_2 norm of some closed-loop transfer function, say of the complementary sensitivity function H_c.

The H_2 norm is defined for any strictly proper rational function G analytic on the imaginary axis as

$$\| G \|_2 = \sqrt{\frac{1}{2\pi} \int_{-\infty}^{\infty} |G(j\omega)|^2 \, d\omega} \,.$$

The set of complementary sensitivity functions that can be achieved in the stabilized control system is

$$H_c = b(y - aW) \,,$$

where W is a free stable rational parameter. The parameter will be selected so as to minimize the H_2 norm of H_c.

Let $\alpha\beta$ be a polynomial defined by keeping the stable (in Re $s < 0$) zeros of ab while replacing the unstable (in Re $s \geq 0$) ones with their negative values. Then $ab/\alpha\beta$ is inner (or all pass) and

$$\| H_c \|_2 = \left\| \frac{\alpha\beta}{ab} H_c \right\|_2 = \left\| \frac{\alpha y \beta}{a} - \alpha W \beta \right\|_2 .$$

Consider the decomposition

$$\frac{\alpha y \beta}{a} = r + \frac{q}{a}$$

where r is a polynomial and q/a is strictly proper. With this decomposition,

$$\| H_c \|_2^2 = \left\| \frac{q}{a} \right\|_2^2 + \| r - \alpha W \beta \|_2^2$$

because q/a and $r - \alpha W\beta$ are orthogonal and thus the cross-terms contribute nothing to the norm. The last expression is a complete square whose first part is independent of W. Hence the minimizing parameter is $W = r/\alpha\beta$, and if it is indeed stable and admissible, it defines the unique optimal controller. Otherwise, no optimal controller exists.

The consequent minimum norm equals

$$\min_W \| H_c \|_2 = \left\| \frac{q}{a} \right\|_2 .$$

Example 8.2 To illustrate, consider the plant $S(s) = 1/(s - 1)$. The class of all stabilizing controllers for S is found to be

$$R(s) = \frac{1 - (s - 1)W}{W}$$

for a free stable rational parameter $W \neq 0$. The complementary sensitivity transfer function is

$$H_c(s) = 1 - (s - 1)W.$$

Now $\alpha = s + 1, \beta = 1$ and the polynomial part of

$$\frac{\alpha y \beta}{a} = \frac{s + 1}{s - 1} = 1 + \frac{2}{s - 1}$$

is $r = 1$. Thus H_c attains minimum H_2 norm for

$$W(s) = \frac{1}{s + 1}$$

and the corresponding optimal controller is $R(s) = 2$.

The optimal complementary sensitivity function is

$$H_c(s) = \frac{2}{s + 1}$$

and $\| H_c \|_2 = \sqrt{2}$.

Robust Stabilization

The notion of robust stability addresses stabilization of plants subject to modeling errors, when the actual plant may differ from the nominal model, using a fixed controller. The ultimate goal is to stabilize the actual plant. The actual plant is

unknown, however, so the best one can do is to stabilize a large enough set of plants.

Thus the basis technique to model plant uncertainty is to model the plant as belonging to a set. Such a set can be either structured – for example, there is a finite number of uncertain parameters – or unstructured: the frequency response lies in a set in the complex plane for every frequency. The unstructured uncertainty model is more important for several reasons. On the one hand, it is well suited to represent high-frequency modeling errors, which are generically present and caused by such effects as infinite-dimensional electromechanical resonance, transport delays, and diffusion processes. On the other hand, the unstructured model of uncertainty leads to a simple and useful design theory.

The unstructured set of plants is usually constructed as a neighborhood of the nominal plant, with the uncertainty represented by additive or multiplicative perturbations. The size of the neighborhood is measured by a suitable norm, most common being the H_∞ norm that is defined for any rational function G analytic on the imaginary axis as

$$\| G \|_\infty = \sup_\omega | G(j\omega) | \ .$$

Let us illustrate the design for *robust stability under unstructured norm-bounded multiplicative perturbations*. Consider a nominal plant with transfer function S and its neighborhood S_Δ defined by

$$S_\Delta := (1 + F\Delta)S$$

where F is a fixed stable rational function and Δ is a variable stable rational function such that $\| \Delta \|_\infty \leq 1$.

The idea behind this uncertainty model is that $F\Delta$ is the normalized plant perturbation away from 1:

$$\frac{S_\Delta}{S} - 1 = F\Delta \ .$$

Hence if $\| \Delta \|_\infty \leq 1$, then for all frequencies ω

$$\left| \frac{S_\Delta(j\omega)}{S(j\omega)} - 1 \right| = | F(j\omega) |$$

so that $| F(j\omega) |$ provides the uncertainty profile while Δ accounts for phase uncertainty.

Now suppose that R is a controller that stabilizes the nominal plant S. Applying the small gain theorem, R is seen to stabilize the entire family of plants S_Δ if and only if

$$\| H_c F \|_\infty < 1.$$

This is a necessary and sufficient condition for robust stabilization of the nominal plant S.

The set of all stabilizing controllers for $S = b/a$ is described by the formula

$$R = \frac{y - aW}{x + bW}$$

where $ax + by = 1$ and W is a free stable rational parameter. The robust stability condition then reads

$$\| b(y - aW)F \|_\infty < 1.$$

Any stable rational W that satisfies this inequality then defines a robustly stabilizing controller R for S. In case W actually minimizes the norm, one obtains the best robustly stabilizing controller.

Example 8.3 Consider a plant with the transfer function

$$S_\tau(s) = \frac{s + 1}{s - 1} e^{-\tau s}$$

where the time delay τ is known only to the extent that it lies in the interval $0 \leq \tau \leq 0.2$. The task is to find a controller that stabilizes the uncertain plant S_τ. The time-delay factor $e^{-\tau s}$ can be treated as a multiplicative perturbation of the nominal plant
$$S(s) = \frac{s + 1}{s - 1}$$

by embedding S_τ in the family

$$S_\Delta := (1 + F\Delta)S$$

where Δ ranges over the set of stable rational functions such that $\| \Delta \|_\infty \leq 1$. To do this, F

**Polynomial/Algebraic
Design Methods, Fig. 2**
Bode plots of F (*dotted*)
and $e^{-0.2s} - 1$ (*solid*)

should be chosen so that the normalized perturbation satisfies

$$\left| \frac{S_\Delta(j\omega)}{S(j\omega)} - 1 \right| = \left| e^{-j\omega\tau} - 1 \right| \le |F(j\omega)|$$

for all ω and τ. A little time with the Bode magnitude plot shows that a suitable uncertainty profile is

$$F(s) = \frac{3s + 1}{s + 9}.$$

Figure 2 is the Bode magnitude plot of this F and $e^{-\tau s} - 1$ for $\tau = 0.2$, the worst value.

The task of stabilizing the uncertain plant S_τ is thus replaced by that of stabilizing every element in the set S_Δ, that is to say, by robustly stabilizing the nominal plant S with respect to the multiplicative perturbations defined by F.

The set of all stabilizing controllers for S is found to be

$$R(s) = \frac{0.5 - (s - 1)W}{-0.5 + (s + 1)W}$$

where $W \ne 0.5/(s + 1)$ is any stable rational parameter. The robust stability condition reads

$$\| P - QW \|_\infty < 1$$

where

$$P(s) = 0.5(s + 1)\frac{3s + 1}{s + 9},$$

$$Q(s) = (s - 1)(s + 1)\frac{3s + 1}{s + 9}.$$

Since Q has one unstable zero at $s = 1$, it follows from the maximum modulus theorem that the minimum of the H_∞ norm taken over all stable rational functions W is $P(1) = 0.4 < 1$ and this minimum is achieved for

$$W(s) = \frac{P(s) - P(1)}{Q(s)} = \frac{1}{10}\frac{15s + 31}{(s + 1)(3s + 1)}.$$

Thus, the robust stability condition is satisfied, and the corresponding best robustly stabilizing controller is

$$R(s) = \frac{2}{13}\frac{s + 9}{s + 1}.$$

Polynomial Equation Approach

In order to determine the set of all stabilizing controllers for a given plant, it is enough to determine one particular solution of the Bézout equation. It is therefore plausible that performance

specifications in addition to stability can be met by selecting an appropriate solution of a polynomial equation that is related to the Bézout equation.

The reduction of controller synthesis to solving polynomial equations is referred to as the *polynomial equation approach* to control system design. The equations involved are Diophantine equations of the form

$$ap + bq = d$$

where a, b, and d are given polynomials and p, q are polynomials to be found. Such an equation is solvable for any d if and only if a and b are coprime polynomials. Then, the solution set is given by

$$p = p_0 + bt, \quad q = q_0 - at$$

where p_0, q_0 is a particular solution and t is an arbitrary polynomial.

Such an equation is in fact the pole placement equation. Thus, pole placement is a prototype control problem.

Pole Placement

The requirement of stability places all closed-loop system poles within the left half-plane Re $s < 0$. Very often, however, we wish to allocate the poles to a specific region of the half-plane or to achieve specific pole positions.

Given a plant $S = b/a$, the set of all stabilizing controllers for S is

$$R = \frac{y - aW}{x + bW}$$

where x, y are polynomials such that $ax + by = 1$ and W is a free stable rational parameter. Let $W = w/d$ for a stable polynomial d. Then

$$R = \frac{dy - aw}{dx + bw} := \frac{q}{p}$$

and the closed-loop pole polynomial is given by

$$ap + bq = d(ax + by) = d.$$

Thus W parameterizes all stabilizing controllers for S, the denominator polynomial d of W specifies the positions of the control system poles, and the numerator polynomial w of W represents the remaining degrees of freedom, i.e., parameterizes all stabilizing controllers that assign the specified poles.

Example 8.4 Consider the plant $S(s) = 1/(s-1)$ and the set of stabilizing controllers for S:

$$R(s) = \frac{1 - (s - 1)W}{W}, \quad W \neq 0.$$

Let the desired pole locations be given by the polynomial $d = s^2 + 2s + 1$. This is achieved by putting $W = w/d$ for an arbitrary numerator polynomial $w \neq 0$.

It is to be noted that d specifies the poles at *finite* positions only. Poles at $s = \infty$ will occur whenever R is not proper rational. To avoid this situation, w should be constrained to $w = s + \omega$ for any real ω. Then the set of controllers that achieve the desired pole placement is

$$R(s) = \frac{(3 - \omega)s + (1 + \omega)}{s + \omega}.$$

Alternatively, one can solve the pole placement equation $ap + bq = d$ directly. The solution set is

$$p = t, \quad q = s^2 + 2s + 1 - (s - 1)t$$

and q/p is proper if and only if $t = s + \omega$, ω real.

H₂ Optimal Control

The H_2 optimal control is a special case of pole placement. Indeed, the optimal controller is given by

$$R = \frac{y - aW}{x + bW} = \frac{y - a\frac{r}{\alpha\beta}}{x + b\frac{r}{\alpha\beta}} = \frac{\alpha y\beta - ar}{\alpha x\beta + br} := \frac{q}{p}$$

and

$$ap + bq = a(\alpha x\beta + br) + b(\alpha y\beta - ar)$$
$$= \alpha\beta(ax + by) = \alpha\beta.$$

Thus, the (finite) pole positions of the H_2 optimal control system are given by the pole polynomial $d = \alpha\beta$. The system has no poles at $s = \infty$ as the optimal complementary sensitivity function H_c is strictly proper.

The pole placement equation, however, has more than one solution. Which one is optimal? The one with q/a is strictly proper. It is the solution pair p, q with q having a least degree.

Example 8.5 Let us reconsider Example 8.2. As an alternative, one can solve the Diophantine equation

$$(s - 1)p + q = s + 1$$

for the solution pair p, q such that $q/(s - 1)$ is strictly proper. This yields the least-degree solution pair with respect to q, namely, $p = 1$, $q = 2$. The optimal controller is $R = q/p = 2$.

Summary and Future Directions

The benefits of representing stabilizing controllers by a single parameter include (1) easy accommodation of additional design specifications by selecting an appropriate parameter, (2) all transfer functions in a stabilized system are linear in the parameter (while they are nonlinear in the controller), and (3) the parameter belongs to a smaller set of stable rational functions (while the controller is any rational).

The results presented here for linear time-invariant systems with rational transfer functions can be generalized to extend the scope of the theory to include distributed-parameter systems, time-varying systems, and even nonlinear systems.

The transfer functions of distributed-parameter systems are no longer rational, and coprime factorizations cannot be assumed a priori to exist. The coefficients of time-varying systems are functions of time, and the operations of multiplication and differentiation do not commute. In nonlinear systems, transfer functions are replaced by input-output maps.

Technical assumptions may prevent one from parameterizing the *entire* set of internally stabilizing controllers; still, the subset may be large enough for practical purposes. For many systems of physical and engineering interest, the above difficulties can be circumvented and the algebraic/polynomial approach carries over with suitable modifications.

Recommended Reading

The use of polynomials, in one way or another, in feedback control system design can be traced back to Newton et al. (1957) and Jury (1958). The authors noted that for a closed-loop system to be stable, H_c must absorb the plant unstable zeros. The plant was assumed to be stable; if this assumption were dropped, H_s would have been found to absorb the plant unstable poles. These conditions are equivalent to polynomial divisibility conditions and hence to the Bézout stability equation, which appears later in Kučera (1974).

The first attempt to use polynomials in an explicit manner is due to Volgin (1962), a student of Tsypkin. He obtained a solution of the pole placement problem through the solution of a polynomial equation, known as the pole placement equation. Åström (1970) published a polynomial equation solution to the minimum variance control problem for minimum-phase plants. The ultimate publication that presents

the polynomial equation approach to multi-input multi-output control system design is Kučera (1979).

The underlying problem in any control system design is that of stability. It is logical to design the control system step by step: stabilization first and then the additional performance specifications. To do this, we need to know any and all stabilizing controllers for the given plant.

This problem was first addressed and solved for finite-dimensional, linear time-invariant systems using transfer function methods; see Larin et al. (1971), Kučera (1975), Youla et al. (1976a,b), and Kučera (1979). A state-space representation of all stabilizing controllers was derived later by Nett et al. (1984).

It took decades to appreciate the importance of the result and come up with applications. The milestones were the observations by Desoer et al. (1980) that the polynomial fraction approach can be extended to linear systems with nonrational transfer functions, as well as the result by Hammer (1985) showing that the approach is applicable to a broad class of nonlinear systems. Further generalizations were obtained by Paice and Moore (1990), Anderson (1998), and Quadrat (2003, 2006).

The parameterization of all controllers that stabilize a given plant was labeled the Youla-Kučera parameterization in Anderson (1998). This result launched an entirely new area of research and has ultimately become a new paradigm for control system design.

Tutorial textbooks on this subject include Vidyasagar (1985), Doyle et al. (1992), and Kučera (2003, 2011). The reader is further referred to the survey papers by Kučera (1993), Anderson (1998), and Kučera (2007).

Advanced and recent applications of the Youla-Kučera parameterization include stabilization under constrained inputs (Henrion et al. 2001), robust stabilization with fixed-order controllers (Henrion et al. 2003), accommodation of time-domain constraints on inputs and outputs (Henrion et al. 2005a), and determination of least-order stabilizing controllers (Henrion et al. 2005b).

Power System Voltage Stability

Costas Vournas
School of Electrical and Computer Engineering, National Technical University of Athens, Zografou, Greece

Abstract

Voltage stability of electric power systems is a challenging topic both theoretically and in practice. This article touches briefly on the main aspects of the problem and highlights theoretical foundations and fundamental methods for voltage stability analysis. The single-load radial system is used to introduce relevant concepts, such as the *PV* curve and the instability mechanism, while the implications for a meshed, multiple-load system are briefly outlined. Some applications to practical problems are briefly enumerated.

Keywords

Introduction

Voltage stability is related to the maximum power transfer in an AC (alternating current) network. In normal conditions, system load demand should never come close to this limit. As, however, electricity demand started swelling after 1970s with an increasingly faster pace, transmission network investments could not follow closely enough. Investment cost in transmission is usually high, and difficulties with environmental constraints and "not in my back yard" mentality of local communities did not make transmission network expansion any easier. Power systems are thus relying for their continuing operation more and more on (reactive power) compensation and automatic controls to maintain transmission capacity of relatively weakening networks.

As a result several instances of voltage instability started to appear in several industrialized countries after the 1980s (Taylor 1994) leading to smaller or larger area blackouts, much to the surprise of the power engineering community that was not prepared to deal with this type of events, in which a usual and expected phase of gradual voltage decline suddenly precipitates to an uncontrollable voltage drop leading to partial or total blackout after a succession of equipment disconnection by protection devices.

In power system engineering practice, voltage drops following load ramping or sudden events, such as equipment loss (line, generator switching, etc.), usually referred to in power engineering literature as contingencies, are calculated by solving a set of nonlinear algebraic equations known as the power flow problem. As these are "steady-state" equations, the dynamic aspect leading to an accelerating, cascading failure is not obvious. One should notice however in the above account the keyword "nonlinear": nonlinear equations at the maximum power transfer limit no longer have a solution. This was and is one of the keys in understanding the voltage stability problem. To take it one step further, close to the loss of solution (loss of equilibrium), a set of dormant (up to this point) dynamics become dominant leading the system to instability. The following sections will explain these notions.
Power System Voltage Stability, Fig. 1 Single-load radial system

Single Generator-Load (Radial) System

Maximum Power Transfer

In any electric network (DC or AC), there is a maximum power that can be transferred between any two nodes. In a two-node radial system, the maximum power transfer coincides with the well-known impedance matching conditions. For a radial AC system, when the load is restricted to a constant power factor, the impedance matching condition is that the source (network) impedance is equal in magnitude to the load impedance.

Consider the radial system of Fig. 1. In this system we assume that the load active power P (and possibly reactive power Q) is fed through a transformer with adjustable tap ratio r (in per unit). The tap is automatically adjusted by a load tap changer (LTC) so as to keep the secondary voltage V_2 within a deadband. We will consider throughout that the LTC is a part of the load.

The simplest case for this radial system is when both the line and transformer are lossless ($P_G = P_1 = P$) and the load is kept to unity power factor ($Q = 0$). The generator is assumed as a constant voltage source E. If we further assume that the transformer leakage reactance is negligible ($Q_1 = Q = 0$ in Fig. 1), the maximum power transfer in this simple case is encountered when the load impedance, as seen from the primary (r^2/G), is equal to the line reactance:

$$X = r^2/G \qquad (1)$$

where the load conductance $G = P/V_2^2$. It can be readily shown that the maximum power in this case is $P_{\max} = E^2/2X$. Note that this is a static condition that is not related to how the load varies with the voltage V_2.

The most popular way of visualizing the maximum power condition is through the *PV* curve of Fig. 2, in which the consumed (transferred) power P is plotted versus the primary (transmission) side voltage V.

In Fig. 2 the nose-shaped solid line is the *network characteristic* corresponding to all possible solution of the network equations for a given P (or V). The maximum power transfer is easily identified as the tip of the curve (point C). Note that *PV* curves can be plotted for any load power factor and line resistance.

Load Dynamics and Voltage Stability

As stated above, maximum power transfer is a static condition based on network equations only. To identify its relation to voltage stability, some form of load dynamics must be introduced. Load dynamics are generally changing the load characteristics so as to adjust load power *consumption* P to a given load *demand* P_o. As a disturbance usually reduces voltage (and thus consumption of a voltage-sensitive load), load dynamics tend to restore the consumption to the pre-disturbance demand.

Load restoration can be continuous, for instance, represented by a time-varying conductance following the ODE:

$$T\dot{G} = \frac{P_o}{V_o^2} - \frac{P}{V_o^2} = \frac{P_o}{V_o^2} - G\left(\frac{V_2}{V_o}\right) \qquad (2)$$

Clearly in this case, the stability condition is that the consumption $P = GV_2^2$ increases with the increase of the load conductance G:

$$\frac{\partial P}{\partial G} > 0 \qquad (3)$$

It is easily verified from Fig. 2 that this condition is met only in the upper part of the *PV* curve before point C, whereas in the lower part, after point C, increased conductance results in lower consumption violating (3). Clearly at C, (3) holds as an equality.

Assuming the load on the secondary side to be a constant admittance, we can distinguish two types of load characteristics in Fig. 2: the

Power System Voltage Stability, Fig. 2 *PV* curve of the radial system
transient (short-term) load characteristic shown with dotted lines corresponds to a specific transformer tap ratio r, whereas the *long-term load characteristic* corresponds to equilibrium conditions where V_2 is within the deadband and approximately equal to V_o and is shown with dashed lines for different load demands.

Load dynamics can also be discrete, e.g., driven by the tap changing transformer of Fig. 1. As the LTC is trying to restore the secondary voltage, it will reduce r when $V_2 < V_o{-}d$ and will increase r when $V_2 > V_o + d$, where d is half of the deadband.

The effect of tap ratio increase in the upper and lower part of the *PV* curve is shown in Fig. 2 (points S and U). In the upper part, increased r will reduce consumption which implies that V_2 is also reduced as expected. In the lower part (point U), increased r will increase consumption indicating an increased V_2 and thus an unstable LTC operation. The stability condition in this case is

$$\frac{\partial V_2}{\partial r} < 0 \qquad (4)$$

Clearly for either discrete or continuous dynamics, at the maximum power point C, a stable and an unstable equilibrium branch come together, leaving no equilibrium points for higher demand. In bifurcation theory this point is known as a saddle-node bifurcation (SNB).

Effect of Generation

The generator behind the constant voltage source E of Fig. 1 supplies the active power consumed by the load (it would cover also active losses, if present). In practice this means that it requires a governor with PI (proportional plus integral) control, as is customary for autonomous systems and a prime mover of the required capacity. The generator also maintains the constant voltage E assumed in the calculations. This requires an automatic voltage regulator (AVR), which can be assumed in this simple example as being also of PI type. The AVR is adjusting the DC rotor (field) current of the synchronous generator so as to maintain the terminal voltage constant.

For a given load, the active and reactive generation $P_G + jQ_G$ required is directly calculated from the network equations. The electromotive force (EMF) corresponding to the field current can then be determined using standard synchronous machine equations and preferably taking into account the saturation of the machine iron core (Van Cutsem and Vournas 1998). It should be noted that due to thermal constraints, it is not possible to exceed a maximum rotor current in continuous operation. This results in a rotor current limit that is enforced by the generator overexcitation limiter (OEL). If loading conditions are such that the OEL is activated, the generator terminal voltage

E cannot be maintained constant, and thus the voltage source *E* has to be replaced by a constant EMF in series with the generator reactance. This leads to a much more restrictive limit for the maximum power transfer.

In power flow calculations, the generator excitation limit is usually represented by a maximum allowable reactive generation $Q_G^{\max}$. When this limit is reached, the reactive generation remains constant, and thus the terminal voltage is allowed to vary, i.e., the generator becomes a PQ bus. Note however that $Q_G^{\max}$ of an actual generator is not constant but depends on terminal voltage and on active generation.

In any case the overexcitation limit of synchronous generators and the resulting limitation of the reactive support they offer is an important factor determining maximum power and thus voltage stability limits. In practice voltage instability is reached only after some critical generators have reached the overexcitation limit.

Voltage Instability Mechanism

Following the preceding discussion, it is possible to describe the mechanism of voltage instability as follows (Van Cutsem and Vournas 1998):

> Voltage instability stems from the attempt of load dynamics to restore power consumption beyond the capability of the combined transmission and generation system.

A voltage instability incident can occur either through a gradual load increase up to the maximum power limit or most commonly following a contingency (or a cascade of contingencies) drastically reducing the maximum power transfer below the pre-contingency demand. Thus, any attempt at restoring power to the pre-contingency demand will induce an unstable response leading to voltage collapse.

As the load dynamics are the driving force of voltage instability, the time scale of load restoration is the one characterizing voltage stability. Thus, fast recovering loads, such as induction motors and power electronics-driven devices, tend to restore load in a second or less and constitute what is known in power system

dynamic analysis as the short-term time scale (Kundur et al. 2004). Study of relevant problems (motor stalling, etc.) is part of *short-term voltage stability* analysis.

In a slower time scale of several seconds up to minutes, load recovery dynamics include the LTCs and thermostatically controlled loads. This is the time scale of *long-term voltage stability* analysis (Kundur et al. 2004). Note that for long-term voltage stability, the short-term dynamics such as those of motors and generators are considered to be in equilibrium. In system representation this assumption leads to the replacement of short-term differential equations with algebraic equilibrium equations. This assumption is known as the quasi-steady-state (QSS) approximation.

Multiple-Load (Meshed) System

The single-load system of Fig. 1 serves well in defining the voltage stability problem and helps visualize its significance through the *PV* curve representation and the maximum loading or critical point C. In actual power systems, however, there are multiple loads defining a multidimensional space where it is sometimes tricky to apply the simple concepts of Fig. 1. For instance, it is important to distinguish between the supply system which can be represented by a Thevenin equivalent and the consumption part where loads affect each other and cannot be examined individually, one at a time.

Consider the power system of Fig. 3, where multiple generators are feeding a number of loads through a meshed network represented by the complex admittance matrix **Y**. The steady-state conditions of the system including generation and load are traditionally represented by the power flow equations:

$$(P_{Gi} + \mathrm{j}Q_{Gi}) - (P_{Ai} + \mathrm{j}Q_{Ai}) - \hat{V}_i$$
$$\sum_{j=1}^{N} \hat{V}_i Y_{ij}^* \hat{V}_j^* = 0 \qquad i = 1, \dots, N \quad (5)$$

Using real variables, (5) can be written as

$$\mathbf{g}(\mathbf{x}, \mathbf{p}) = 0 \qquad (6)$$

Power System Voltage Stability, Fig. 3 Meshed power system
where **p** is the vector of independent parameters (load demands, generator setpoints) and **x** the vector of dependent variables (voltages and angles).

Note that in this representation, the load is referred to the primary side of LTC transformers as in Fig. 1. This can be considered constant at equilibrium corresponding, for instance, to secondary (distribution side) voltage restoration at its setpoint value $V_{Bi} = V_{oi}$.

Concerning generators the active power P_{Gi} cannot be treated as constant when load is varying, so there has to be a participation factor attached to each generator bus that will represent primary or secondary frequency regulation characteristic (Van Cutsem and Vournas 1998). This is sometimes referred to as the *distributed slack bus* approach. For reactive power the limits $Q_{Gi}^{\max}$ of reactive support should be set, beyond which the generator voltage is no longer constant (switch from *PV* to *PQ* bus).

The solution of the N nonlinear complex equations (5) for a given load demand determines all complex voltages in the system. As in the simple radial system case, there may exist multiple solutions, some of which unstable, or no solutions at all. The stability limits, where (3) and (4) hold as equalities for the radial system, are now given by the singularity of the Jacobian of the equilibrium conditions (6):

$$\det \mathbf{D_x g} = 0 \qquad (7)$$

The stability limit can be determined also by the singularity of the state matrix (Medanic et al. 1987; Van Cutsem and Vournas 1998):

$$\det \mathbf{A} = \det \left[\frac{\partial V_i}{\partial r_j} \right] = 0 \qquad (8)$$

Note that the impedance matching condition for a single load amounts to the diagonal element $a_{ii} = 0$ which is much more strict than the singularity condition (8) that marks the actual onset of instability. The points satisfying (7) and (8) are critical points and form a multidimensional manifold in parameter space called *bifurcation surface*.

Applications

The above analysis briefly touches on fundamentals. Detailed analysis tools for voltage stability include (but are not limited to) continuation power flow, VQ curves, time simulation (short-term, long-term, QSS), sensitivity, and eigenvalue/singular value analysis. Voltage security analysis is presently applied online in various control centers based on the above methods of analysis for a large number of contingencies. Countermeasures to voltage instability and collapse cover a wide spectrum, from automatic reactive devices switching to special protection controls and load shedding as a last resort. Further details can be sought in textbooks Taylor (1994) and Van Cutsem and Vournas (1998).

Powertrain Control for Hybrid-Electric and Electric Vehicles

Giorgio Rizzoni
Department of Mechanical and Aerospace Engineering, Center for Automotive Research, The Ohio State University, Columbus, OH, USA

Abstract

Powertrain electrification and hybridization have rapidly become part of the portfolio of all major automotive manufacturers, ranging from hybrid-electric, to plug-in hybrid-electric, to battery-electric vehicles, to hybrid-hydraulic and hybrid-mechanical solutions. The increased complexity of the powertrain systems associated with hybrid vehicles presents interesting control challenges and problems, and this entry describes the more common architectures of hybrid-electric

vehicle powertrains and their operation, focusing on the important problem of optimal control for energy management of hybrid-electric vehicles, on mode switching, and on battery management. In the conclusion, a connection is made between these problems and their interaction with intelligent transportation systems.

Keywords

Introduction

Increasingly stringent fuel economy and emissions regulations have required the automotive industry to consider more fuel-efficient powertrains and alternative primary sources of transportation fuels. Powertrain electrification and hybridization have rapidly become part of the portfolio of all major automotive manufacturers, ranging from hybrid-electric, to plug-in hybrid-electric, to battery-electric vehicles, to hybrid-hydraulic and hybrid-mechanical solutions. The increased complexity of the powertrain systems associated with hybrid vehicles presents interesting control challenges and problems. This entry describes control problems associated with hybrid-electric vehicles (HEVs) and battery-electric vehicles (BEVs).

HEV Powertrains

An HEV powertrain contains at least two power sources: a primary engine – typically a combustion engine or a fuel cell fueled by a chemical fuel (in liquid or gaseous form) – and a secondary power source that makes use of a rechargeable energy storage system (RESS) that permits buffering the power demand of the vehicle so as to provide choices in the use of the power sources. While it is possible to design hybrid powertrains using secondary hydraulic or mechanical energy conversion and storage devices (hydraulic pump/motors and accumulators, mechanical flywheels), the majority of hybrid
Powertrain Control for Hybrid-Electric and Electric Vehicles, Fig. 1 Hybrid powertrain configurations (After Rizzoni and Peng (2013), courtesy: Dr. Chiao-Ting Li, the University of Michigan)

powertrains in use today employ electric machines and electrochemical energy storage devices (batteries and supercapacitors); thus, this entry focuses exclusively on *hybrid-electric* vehicles (HEVs). Electric vehicles (EVs) can be viewed as a special case of HEVs in which no internal combustion engine is present, and many of the considerations that follow apply also to hydraulic and mechanical hybrids. HEVs may be classified according to their powertrain architecture as shown in Fig. 1.

A *series HEV powertrain* employs an electric machine (EM) to propel the vehicle while using an internal combustion engine (ICE) coupled to a second EM as an electrical generator set. In a series HEV, the electrical generator set can provide power directly to the electric traction

system, via an electrical DC bus, or can charge an RESS (e.g., battery), or can perform both functions Motive power to the vehicle is delivered by the primary EM. Thus, a series HEV blends electrical power from an RESS with electrical power generated by an ICE-powered generator set to provide motive power to the vehicle. Deciding how much electrical power to draw from each of the two power sources to meet the power demand of the vehicle is an important control objective. A further feature of interest is the ability to recover some of the kinetic energy of the vehicle during braking events by using the traction EM in generator mode to recharge the RESS.

A *parallel HEV powertrain* blends mechanical power from the ICE and one or more EMs

P

through appropriate mechanical coupling and transmission elements to deliver motive power to the vehicle or to recharge the RESS. In a parallel HEV powertrain, the same EM is used to provide power to the vehicle (motor mode) and to provide energy to the RESS (generator mode); in the latter case, the RESS can be recharged either by providing power from the ICE in excess of that required by the vehicle or by converting the kinetic energy of the vehicle into electrical power through the braking action of the EM.

A third configuration, the one that is most commonly found among passenger vehicles in commercial production today, is the *power-split HEV*, in which the benefits of both series and parallel HEVs are achieved most commonly by using one or more planetary gear sets to couple two EMs – to the ICE on one side and to the driveline on the other.

Regardless of architecture, HEV powertrains enable fuel savings and emissions reductions by operating in a variety of modes that include *load leveling*, *regenerative braking*, *engine start-stop*, and *transmission optimization* (Miller 2004; Rizzoni and Peng 2013). All of these functions benefit from the availability of an RESS and of bidirectional power converters, that is, the electric drive system(s) that can serve both motor and generator functions.

HEV Operation

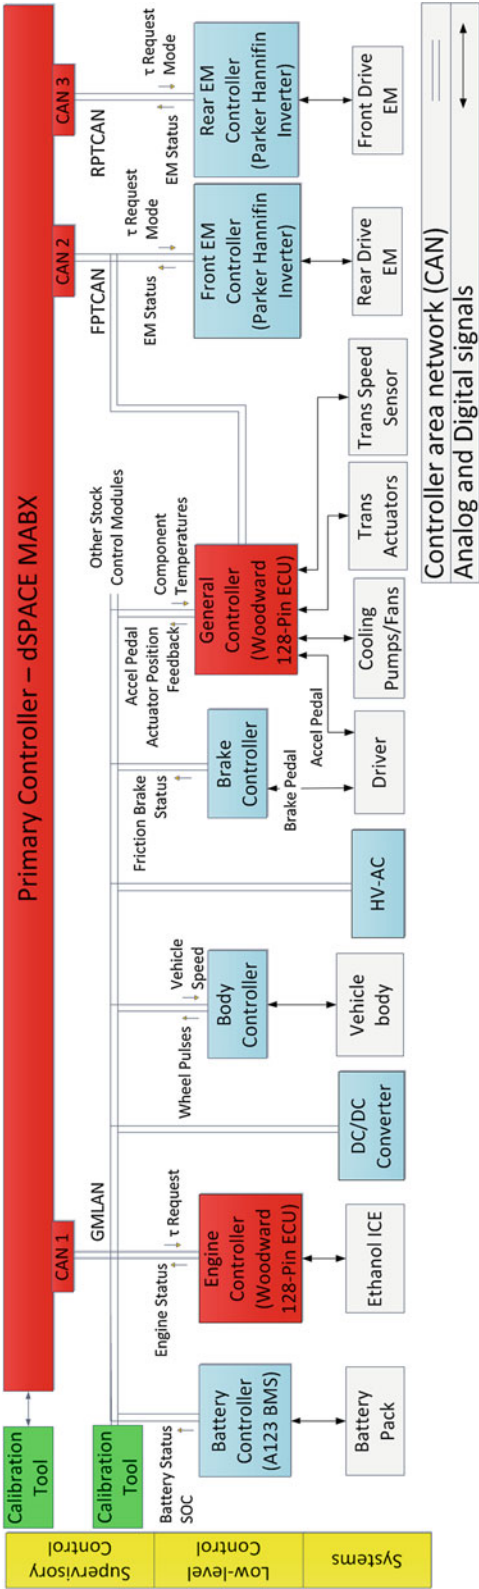
An HEV is considered *charge sustaining* if the RESS is recharged only by power supplied by the ICE or by regenerative braking. If, on the other hand, the vehicle is designed to deplete energy stored in the RESS during the course of a trip, ending the trip with a lower state of stored energy than at the start and requiring recharging from the electrical grid, the vehicle is called *charge depleting* and is commonly referred to as a *plug-in HEV* (PHEV). PHEVs can in turn be subdivided into blended-mode PHEVs, in which stored electrical energy and fuel chemical energy are used jointly to achieve minimum overall energy use, and extended-range electric vehicles (EREVs), in which electrical energy is used exclusively to power the vehicle, until a lower bound is reached,

at which point the vehicle uses both ICE and EM(s) to behave like a charge-sustaining hybrid. In principle, any of the architectures of Fig. 1 can be used in any of these modes. A battery-electric vehicle, or BEV, is an extreme case of an EREV, in which the vehicle is not equipped with an ICE. Miller (2004) provides an excellent overview of the technology underlying each of the powertrain architectures mentioned so far.

Control Problems in X-EVs

Let us refer to the general case of a hybrid or electric vehicle as an X-EV, with the X in X-EV representing any of the architecture discussed so far: X− = H, PH, ER, or B. X-EVs enable multiple configurations and operating modes of the powertrain, presenting a number of interesting control problems above and beyond those that are already present in non-hybrid powertrains (e.g., engine and transmission control). In general, the control architecture of an HEV is hierarchical, with a higher-level (supervisory) controller that manages the power flows and mode changes (e.g., from electric to hybrid in an EREV) to meet the vehicle fuel economy, emissions, performance, and drivability requirements. Figure 2 depicts a hierarchical control architecture in use in a prototype PHEV.

In an X-EV, two problems are especially important: *optimal energy management*, that is, the ability to optimize the energy use of a vehicle during a trip, and *mode switching*, that is, the ability to select the appropriate operating mode and to smoothly switch between modes.

The higher-level controller issues set points to lower-level controllers that are used to manage the ICE, the EM(s), the mechanical transmission system, the brake system, and the RESS, as well as other auxiliary functions in the vehicle. In this article we primarily consider the higher-level controller and focus on two problems that are especially relevant to HEVs: *optimal energy management* and *mode switching*. In addition, we also consider the battery controller (often called *battery*


Powertrain Control for Hybrid-Electric and Electric Vehicles, Fig. 2 Hierarchical structure of an HEV controller (Courtesy: The Ohio State University EcoCAR 2 Team)

P

management system or BMS), which while being a low-level control is very specific to X-EVs.

Optimal Energy Management

The optimal energy management problem in an X-EV consists of finding the control $u(t)$ that leads to the minimization of a performance index J over the time horizon $t - t_f$, corresponding to a driving cycle, or *trip*; the problem is subject to constraints that are related:

(i) To physical limitations of the actuators and the energy stored in the RESS
(ii) To the requirement to maintain the RESS state of energy within prescribed limits (in a charge-sustaining X-EV) or to track a specified RESS stored energy trajectory (in charge-depleting X-EVs)

Let $L(\cdot)$ be a suitable function of the system states and inputs that accounts for the quantities we wish to minimize, for example, fuel consumption or emissions of carbon dioxide. Then, we define the cost function

$$J(x(t), u(t)) = \int_{t_0}^{t_f} L(x(t), u(t), t) dt \quad (1)$$

which is to be minimized for every trip. In general, the exact driving cycle, or profile, associated with a trip is not completely known; thus, a causal solution to this problem is impossible to achieve without making some assumptions. Various approaches to solve (1) have been proposed over the years; we cite (i) dynamic programming (DP), (ii) local optimization solutions as surrogates of a global solution, (iii) Pontryagin's minimum principle (PMP), and (iv) rule-based methods. Onori et al. (2014) provide a comprehensive overview of the problem as well as detailed examples. We briefly review approaches (i), (ii), and (iii) in the present article.

Global Optimization by Dynamic Programming

If the driving cycle, represented by the vehicle instantaneous velocity over time, $v(t)$ is known, it is possible to cast (1) in such a form that

a DP solution is possible. For example, in a charge-sustaining X-EV, one can find the sequence of inputs that minimizes the trip fuel consumption while sustaining the desired state of charge of a battery and meeting the speed profile of the vehicle. In this problem, the input is the power supplied by the battery to the electric machine, and the state of charge of the battery, SOC, is the only state; all other subsystems (engine, electric drives, transmission, etc.) are modeled via quasi-static efficiency models that can be represented by algebraic equations (e.g., Willans lines, Rizzoni et al. 1999) or by maps. The vehicle velocity profile, $v(t)$ is converted to a vehicle power request, $P_{REQ}(t)$, knowing the vehicle load characteristics (aerodynamic, inertial, rolling and drivetrain friction, and road grade). In turn, the power required to meet a specific load profile is the sum of the power delivered by the ICE and EM, $P_{REQ}(t) = P_{ICE}(t) + P_{BAT}(t)$. So, for example, we seek the control input, $P_{BAT}(t)$, that corresponds to the minimum fuel consumption, that is, $\min\limits_{\{P_{ICE}(t), P_{BAT}(t) \forall t\}} \int_{t_0}^{t_f} \dot{m}_f(t) dt$, while delivering the requested vehicle power. The problem has physical constraints in the actuators (maximum and minimum power that can be delivered by ICE and EM), as well as the requirement for the control policy to be charge sustaining, which is translated into the additional condition $SOC(t_0) = SOC(t_f)$. While this is only a sketch of the problem formulation (see Onori et al. (2014) for a detailed treatment), it should be clear that it is possible to find a DP solution. If the vehicle is charge depleting, the problem can be similarly formulated with $SOC(t_f) < SOC(t_0)$.

In practice, this approach requires complete information of the vehicle velocity profile, and DP is not an implementable, causal solution to the X-EV energy management problem. It is, however, a very useful tool to establish a benchmark for a problem or as an aid in developing a rule base (Onori et al. 2014). Stochastic DP methods have been proposed to circumvent the need to know the driving cycle exactly (see, e.g., Tate et al. 2007).

Local Optimization by Equivalent Fuel Consumption Minimization

A heuristic approach that has met with success is to solve (1) as a local optimization problem, wherein $\int_{t_0}^{t_f} \min_{\{P_{ICE}(t), P_{BAT}(t) \, \forall t\}} \dot{m}_f(t) dt$ is used as an approximation for $\min_{\{P_{ICE}(t), P_{BAT}(t) \, \forall t\}} \int_{t_0}^{t_f} \dot{m}_f(t) dt$. This approach gives rise to the *Equivalent fuel Consumption Minimization Strategy* (ECMS) (Paganelli et al. 2001), which accounts for the use of stored electrical energy, in units of chemical fuel use (g/s), such that one can define an "equivalent fuel consumption" taking into account the cost of the electrical energy used to produce $P_{BAT}(t)$ by way of the fuel that must be used at a future time to replenish the stored electrical energy in the RESS. The equivalent fuel consumption is defined in (2):

$$\dot{m}_{f,eq}(t) = \dot{m}_f(t) + \dot{m}_{eq}(t) = \dot{m}_f(t)$$
$$+ s(t) \frac{E_{batt}}{Q_{LHV}} S\dot{O}C(t) \quad (2)$$

In (2), $\dot{m}_{f,eq}$ is the equivalent fuel consumption, $\dot{m}_f$ is the actual chemical fuel consumption, $\dot{m}_{eq}$ is the virtual fuel consumption corresponding to the use of electricity stored in the battery (to be replenished in the future), E_{BAT} is the energy capacity of the battery, Q_{LHV} is the lower heating value of the chemical fuel, and $s(t)$ is the *equivalence factor* that assigns a cost to the use of electricity. Then, the global minimization problem of (1), with $L(\cdot)$ equal to $\dot{m}_{f,eq}$, becomes the problem of finding $\int_{t_0}^{t_f} \min_{\{P_{ICE}(t), P_{BAT}(t) \, \forall t\}} \dot{m}_f(t) dt$. This approach, which can be easily implemented, has been used widely and has been shown to closely approximate the global optimal solution if sufficient knowledge of the vehicle driving cycle is available. The method does requires empirical calibration and tuning of the equivalence factor, $s(t)$, the optimal value of which is dependent on the driving cycle. Such calibration could be automated by using a predictor to generate a short-horizon estimate of the driving cycle and an adaptor to generate an appropriate $s(t)$ (Musardo et al. 2005).

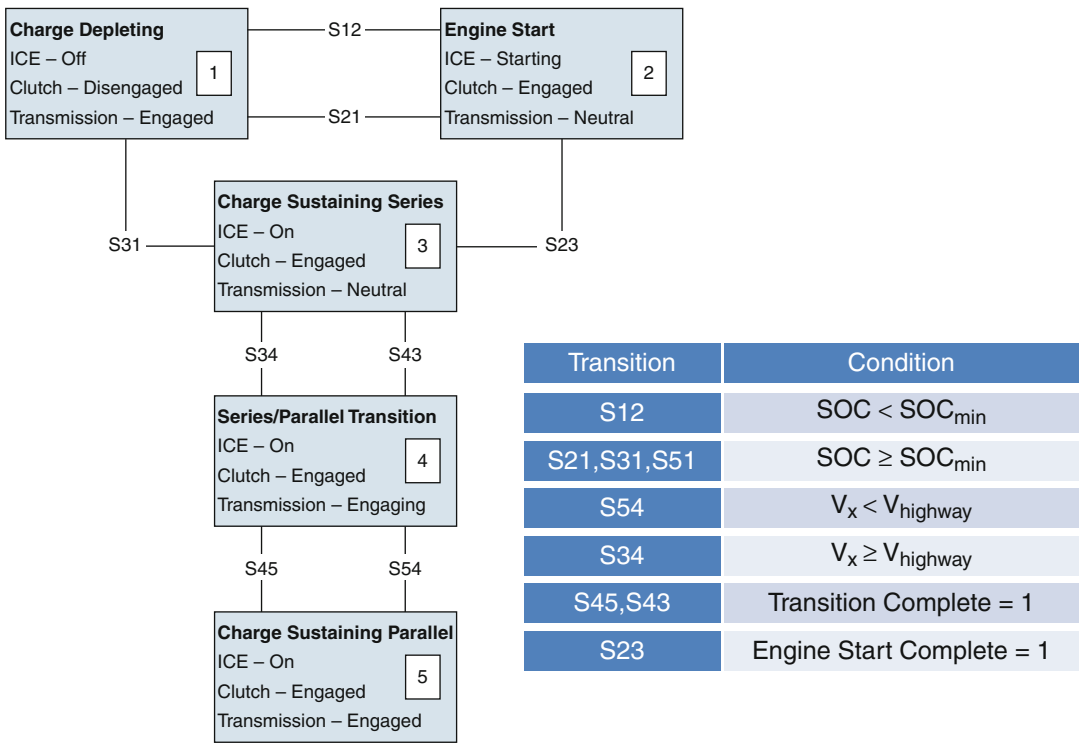
Optimization by Pontryagin's Minimum Principle

Pontryagin's minimum principle (PMP) can also be employed to solve the X-EV energy management problem. If, again, the fast dynamics of the system are neglected the state equation is

$$\dot{x}(t) = f(x, u, t) = -\frac{1}{E_{BAT}} I_{BAT}(x, u, t) \quad (3)$$

where $x = SOC$ is the state of charge of the battery, E_{BAT} is the energy capacity of the battery, and I_{BAT} is the instantaneous battery current. If the input is the power requested of the battery, $P_{BAT}(t)$, which in turn determines the engine power request, $P_{ICE}(t)$, and hence the fuel consumption, then the Hamiltonian function can be defined to be

$$H(x(t), P_{BAT}(t), \lambda(t)) = \dot{m}_f(P_{BAT}(t)) - \lambda(t) \cdot$$
$$f(x(t), P_{BAT}(t), t) \, (4)$$

In (4), $f(\cdot)$ is given by Eq. (3), and the control $P_{BAT}(t)$ that which minimizes Eq. (4) at each time instant is


$$P_{BAT}^*(t) = \arg\min_{P_{BAT}} H(x(t), P_{BAT}(t), \lambda(t)) \quad (5)$$

The co-state variable, $\lambda(t)$, is the solution of

$$\dot{\lambda}(t) = -\lambda(t) \frac{\partial f(x(t), u(t))}{\partial x} \quad (6)$$

Eqs. 3 and 5, with boundary conditions $x(t_0)$ and $x(t_f)$, can be solved numerically; in Serrao et al. (2009, 2011) it is shown that the co-state $\lambda(t)$ is related to the *equivalence factor* of Eq. (2), confirming that the intuitive ECMS solution is in fact the PMP solution, providing that the equivalence factor (or co-state) is time varying and satisfies

$$H(t, x, u, \lambda) = \dot{m}_f + \lambda(t)\dot{x}(t) \quad \text{and}$$
$$s(t) = -\lambda(t) \frac{Q_{LHV}}{E_{BAT}} \quad (7)$$

Powertrain Control for Hybrid-Electric and Electric Vehicles, Fig. 3 State diagram illustrating mode switching in a PHEV (Courtesy: The Ohio State University EcoCAR 2 Team)

The PMP solution is also cycle dependent, as the optimal initial condition for the co-state is dependent on the driving cycle. This dependence on the driving cycle, whether expressed in terms of an equivalent fuel consumption in the ECMS solution or as the initial condition of the co-state in the PMP solution, is an unavoidable consequence of the fact that the fuel consumption of a vehicle is strongly dependent on the driving conditions, which affect the vehicle load.

The basic concepts outlined above continue to be the subject of further development; for example, integrating available trip information available from navigation and geographical information systems into predictive energy management algorithms and considering battery aging as a cost in the optimization function are but two of the research areas being pursued.

Mode Switching

X-EV architectures permit multiple operating modes to exploit the design and control flexibility available in the powertrain. Some examples are the following: an X-EV could operate in pure EV mode or in hybrid mode (whether series, parallel, or power-split), could use special control algorithms during regenerative braking events to provide maximum energy recovery without adversely affecting brake and vehicle stability control systems, and could implement special start-stop control strategies that minimize fuel consumption at idle without adversely affecting engine cold- or warm-start emissions and without inducing unwanted transient vibrations (Canova et al. 2009). Figure 3 depicts an example of a state flow diagram that could be implemented in a finite state machine. Mode switching can result in *drivability* problems (Wei and Rizzoni 2004), that is, in undesirable

transient response characteristics during mode changes. An X-EV can, in this context, be represented as a hybrid system (Koprubasi et al. 2007).

Battery Management Systems

The most common RESS in hybrid vehicle is the electrochemical battery. A hybrid or electric vehicle uses a battery pack that is typically composed of modules, which are in turn comprised of battery cells connected in series and parallel. Battery management systems are necessary to provide charge balancing, cell protection, state of charge and state of health estimation, and other functions related to the management of the stored energy. A good overview of battery systems and associated control problems may be found in Rahn and Wang (2013).

Two important problems related to battery management are state of charge (SOC) and state of health (SOH) estimation. SOC estimation is a necessary component of any battery management system. The SOC of battery is defined by the following equations, in which x is the SOC, Q_{BAT} is the battery capacity in ampere-hours, and η is the battery charging/discharging efficiency:

$$\dot{x}(t) = \frac{\eta}{Q_{BAT}(t)} \cdot I_{BAT}(t) \quad x(t) = x(t_0)$$

$$+ \frac{1}{3,600 \cdot Q_{BAT}(t)} \int_{t_0}^{t_f} I_{BAT}(\tau) \cdot d\tau \quad (8)$$

In practice, there are two problems with using current integration (also called *Coulomb counting*) to estimating SOC: (i) errors in numerical integration accumulate and may cause significant bias error in the estimate, and (ii) the actual capacity of the battery is unknown during vehicle operation, as it changes over time due to battery aging. A second SOC estimation approach consists of correlating the battery open-circuit voltage to the SOC, but this approach also suffers from significant uncertainty, as the open-circuit voltage-SOC correlation curves are only accurate in stationary conditions (constant temperature, with battery at rest). SOC estimation has been the subject of

much research and has seen the use of Kalman filters, extended Kalman filters, particle filters, and other estimation approaches (Chaturvedi et al. 2010).

The SOH of a battery degrades over time due to two principal factors: *capacity fade* and *power fade* (which can also be thought of as *conductance fade* caused by an increase in the internal resistance of the battery). These phenomena are the result of complex electrochemical interactions that are specific to battery chemistry. The ability to estimate the capacity and resistance of a battery during actual operation is a very important aspect of battery management. As in the case of SOC estimation, no direct measurement is possible outside of controlled laboratory conditions; hence, estimation algorithms must be employed (Chaturvedi et al. 2010). It is important to observe that SOC and SOH estimation algorithms operate on two completely different time scales, as the SOC of a battery fluctuates over time windows of minutes or hours, while the SOH changes very slowly over time, with measurable changes occurring over periods of months or years.

Summary and Future Directions

In summary, the control of X-EV powertrains is a rich subject for control theoreticians and practitioners, presenting topics related to optimization and optimal control (for energy management, battery aging), hybrid control (for drivability), adaptive and predictive control, and estimation. Further, the electrification of ground vehicles presents interesting opportunities to integrate vehicles with the electric power and communication networks infrastructures. The following paragraphs describe two such opportunities.

Vehicle-Grid Interaction

As the penetration of plug-in vehicles, PHEVs and BEVs, increases, their impact on the electric power grid cannot be neglected; the consideration of increased electric power demand and of the

timing of vehicle charging must be included in the control/optimization of the electric power grid.
